^a Ramelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolism. CYP1A2 is the major enzyme involved in oxidative metabolism; CYP3A and CYP2C9 also are involved as minor enzymes. Remarkable elevation in C _{max} and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor fluvoxamine. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/5th to 1/10th the affinity of ramelteon as an agonist for the melatonin receptors (MT-1 and MT-2); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon. ^b Poor systemic availability of ramelteon is due to extensive first-pass metabolism. C _{max} and AUC are elevated by a high-fat meal; T _{max} is slightly delayed. ^c Intersubject variability is notably large.				^d Four- and 10-fold elevation in AUC in mild and moderate hepatic impairment. ^e P = parent drug; M = M-II metabolite. ^f C _{max} following a single 16-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug or active metabolite because of their short elimination t _{1/2} . <i>References:</i> Drugs@FDA. Rozerem label approved on 10/20/08. Riluzole. <i>Lancet</i> , 1996 , 348:795–799.			
Risperidone ^a							
PO: 66 ± 28 ^b IM: 103 ± 13	3 ± 2 ^b	89 ^c	5.4 ± 1.4 ^b ↓ RD, ^a Aged ^d	1.1 ± 0.2	3.2 ± 0.8 ^{a,b} ↑ RD, ^a Aged ^d	R: ~1 ^e	R: 10 ng/mL ^e TA: 45 ng/mL ^e
^a The active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a t _{1/2} of 20 ± 3 hours. In extensive metabolizers, 35 ± 7% of an IV dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. ^b Formation of 9-hydroxyrisperidone is catalyzed by CYP2D6. Parameters reported for extensive metabolizers. In poor metabolizers, <i>F</i> is higher; ~20% of an IV dose is excreted unchanged, 10% as the 9-hydroxy metabolite; <i>CL</i> is slightly <1 mL/min/kg, and t _{1/2} is similar to that of the active metabolite, ~20 hours. ^c 77% for 9-hydroxyrisperidone. ^d Changes in elderly subjects due to				decreased renal function affecting the elimination of the active metabolite. ^e Mean steady-state C _{min} for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3-mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers. <i>References:</i> Cohen LJ. Risperidone. <i>Pharmacotherapy</i> , 1994 , 14:253–265. Heykants J, et al. The pharmacokinetics of risperidone in humans: A summary. <i>J Clin Psychiatry</i> , 1994 , 55(suppl):13–17.			
Ritonavir ^a							
— ^b ↑ Food	3.5 ± 1.8	98-99	SD: 1.2 ± 0.4 ^c MD: 2.1 ± 0.8 ^c ↓ Child, LD ^d	0.41 ± 0.25 ^c	3-5 ^c ↓ LD ^d	2-4 ^e	11 ± 4 µg/mL ^e
^a Ritonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own <i>CL</i> with single-dose (SD) to multiple-dose (MD) administration. ^b Absolute bioavailability unknown (>60% absorbed); food elicits a 15% increase in oral AUC for capsule formulation. ^c <i>CL/F</i> , <i>V_{area}</i> / <i>F</i> , and t _{1/2} reported for oral dose. ^d <i>CL/F</i> reduced slightly and t _{1/2} increased				slightly, moderate liver impairment. ^e Following a 600-mg oral dose given twice daily to steady state. <i>References:</i> Hsu A, et al. Ritonavir. Clinical pharmacokinetics and interactions with other anti-HIV agents. <i>Clin Pharmacokinet</i> , 1998 , 35:275–291. <i>PDR54</i> , 2000 , p. 465.			

Rivastigmine^a

72 (22-119) ^b ↑ Food, Dose	Negligible	40	13 ± 4 ^c	1.5 ± 0.6 ^c	1.4 ± 0.4 ^{c,d}	1.2 ± 1.0 ^e ↓ Food	26 ± 10 ng/mL ^e ↓ Food
^a Rivastigmine is metabolized by cholinesterase. No apparent gender differences. ^b Following a 6-mg oral dose. Bioavailability increases with dose; following a 3-mg dose, the median bioavailability is 36%. ^c IV dose of 2 mg. ^d The pharmacodynamic t _{1/2} is ~10 hours due to tight binding to acetylcholinesterase. ^e Following oral administration of a 6-mg capsule. C _{max} increases more than proportionally at doses >3 mg.				<i>References:</i> Hossain M, et al. Table AII-1

Pharmacokinetic Data (Continued)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATION
Solifenacin ^a							
90	3-6	98% ^b	9.39 ± 2.68 ↓ LD, RD ^c	671 ± 118	52.4 ± 13.9 ↓ LD, RD ^c	4.2 ± 1.8 ^c	40.6 ± 8.5 ng/mL ^d
^a Solifenacin is extensively metabolized by CYP3A. The 4R-hydroxy-solifenacin metabolite is pharmacologically active but not likely to contribute to the therapeutic efficacy of solifenacin because of low circulating levels. ^b Primarily bound to α ₁ -acid glycoprotein. ^c Dosage reduction is advised in patients with severe renal impairment (CL _{cr} <30 mL/min), in whom a 2-fold reduction in clearance and prolongation in t _{1/2} are expected. ^d At steady state following 21 days of dosing with 10 mg once daily. <i>References:</i> Drugs@FDA. ^a Drug disposition parameters calculated from blood concentrations. Data from liver transplant patients reported. Metabolized by CYP3A; also a substrate for P-glycoprotein. ^b A similar bioavailability (<i>F</i> = 21 ± 19%) reported for kidney transplant patients; <i>F</i> = 16 ± 7% for normal subjects. Low oral bioavailability likely due to incomplete intestinal availability. ^c Different values for plasma protein binding reported. Concentrates in blood cells; blood-to-plasma concentration ratio = 35 (12-67). ^d Slightly higher <i>V_{ss}</i> and <i>t</i> _{1/2} reported for kidney transplant patients. Because of the very high and variable blood-to-plasma concentration ratio,				markedly different <i>V_{ss}</i> values are reported for parameters based on plasma concentrations. ^e Following a single 7-mg oral dose given to healthy adults. Consensus target <i>C_{min}</i> at steady state are 5-20 ng/mL. <i>References:</i> Bekersky I, et al. Dose linearity after oral administration of tacrolimus 1-mg capsules at doses of 3, 7, and 10 mg. <i>Clin Ther</i> , 1999 , 27:2058–2064. Jusko WJ, et al. Pharmacokinetics of tacrolimus in liver transplant patients. <i>Clin Pharmacol Ther</i> , 1995 , 57:281–290. <i>PDR54</i> , 2000 , pp. 1098–1099.			
Tadalafil ^a							
—	—	94	0.59 ^b ↓ RD ^c	0.89 ^b	17.5	2 ^d	378 ng/mL ^d
^a Eliminated primarily by CYP3A4-dependent metabolism. ^b <i>CL/F</i> and <i>V/F</i> reported. ^c AUC increased in patients with mild or moderate (2-fold) and severe (4-fold) renal insufficiency. ^d Following a single 20-mg oral dose.				<i>References:</i> Curran M, et al. Tadalafil. <i>Drugs</i> , 2003 , 63:2203–2212; discussion 2213–2214. Product labeling: Cialis® (tadalafil tablets). Bothell, WA, Lilly Icos, 2004 .			

Tamoxifen^a

—	<1	>98	1.4 ^{b,c}	50-60 ^b	4-11 days ^d	5 (3-7)	120 (67-183) ng/mL
---	----	-----	--------------------	--------------------	------------------------	---------	--------------------

^aHas active metabolites; 4-hydroxytamoxifen and 4-hydroxy-*N*-desmethyltamoxifen are minor metabolites that exhibit affinity for the estrogen receptor that is greater than that of parent *trans*-tamoxifen. The $t_{1/2}$ of all metabolites are rate limited by tamoxifen elimination.

^b CL/F and V_{area}/F reported. ^cThe major pathway of elimination, *N*-demethylation, is catalyzed by CYP3A. ^d $t_{1/2}$ consistent with accumulation and approach to steady state. Significantly

longer terminal $t_{1/2}$ s are observed. ^eAverage C_{ss} following a 10-mg oral dose given twice daily to steady state.

Toremifene^a

—	Negligible	99.7	2.6 ± 1.2 L/hr/m ² ^b ↓ LD, ^c RD	479 ± 154 L/m ² ^b ↑ Aged	T: 148 ± 53 ^b DMT: 504 ± 578 ^b ↑ Aged, LD	T: 1.5-3 ^d DMT: 3-6 ^d	T: 1.1-1.3 µg/mL ^d DMT: 2.7-5.8 µg/mL ^d
---	------------	------	---	---	---	--	--

^aData from healthy adult male and female subjects and female patients with breast cancer. Toremifene (T) is metabolized by CYP3A to *N*-desmethyltoremifene (DMT), a metabolite that accumulates in blood and has anti-estrogenic activity. Toremifene appears to undergo enterohepatic recycling, prolonging its apparent $t_{1/2}$. ^b*CL/F*, V_{area}/F , and $t_{1/2}$ reported for oral dose. ^c*CL/F* reduced, hepatic cirrhosis or fibrosis. ^dFollowing a 60-mg oral dose given once daily to steady state in patients with breast cancer.

Vardenafil^a

15 (8-25)	2-6	93-95 (parent and M1)	56	3.0 ^b	4-5 (parent and M1)	0.7 (0.25-3) ^c	19.3 ± 1.7 ng/mL ^c
-----------	-----	-----------------------	----	------------------	---------------------	---------------------------	-------------------------------

^aVardenafil is primarily metabolized by CYP3A with minor involvement of CYP2C9. The major oxidative metabolite (M1), a product of *N*-desmethylation at the piperazine ring, is a less potent PDE5 inhibitor and circulates at a level 28% that of the parent drug. It contributes only 7% of the *in vivo* activity of vardenafil. ^b V_{ss} of 208 L, assuming 70-kg bodyweight. ^cFollowing a single 20-mg dose. There is no change in pharmacokinetics between single and multiple dosing.

References: Drugs@FDA. Levitra label approved on 3/19/08. Available at: <http://www.access-data.fda.gov/scripts/cder/drugsatfda/index.cfm>. Accessed on December 31, 2009. Gupta M, et al. The clinical pharmacokinetics of phosphodiesterase-5 inhibitors for erectile dysfunction. *J Clin Pharmacol*, **2005**, 45:987–1003.

Varenicline^a

≥87% ^b	86.2 ± 6.2	≤20	2.27 ± 0.34 ^c	6.2 ^c	31.5 ± 7.7 ^c	2.0 (1.0-4.0) ^d	10.2 ± 1.0 ng/mL ^d
-------------------	------------	-----	--------------------------	------------------	-------------------------	----------------------------	-------------------------------

^aVarenicline is eliminated mostly by renal excretion with minimal metabolism. Organic Cation Transporter 2 (OCT2) is involved in renal tubular secretion, as evidenced by inhibition of varenicline renal clearance by cimetidine, a known OCT2 inhibitor. ^b87.1 ± 5.5% of radioactivity is excreted in urine after an oral dose of [¹⁴C]-varenicline. Minimal first-pass metabolism is expected. ^c CL/F and V_z/F estimated from steady-state AUC and $t_{1/2}$ during 1-mg twice-daily dosing of varenicline in healthy adult smokers and assuming an average body weight of 70 kg. ^dAfter the first dose of a multiple-dosing regimen. An accumulation factor of 2.85 ± 0.73 was reported.

Table AII-1

Pharmacokinetic Data (Continued)

BIOAVAILABILITY (ORAL) (%)	URINARY EXCRETION (%)	BOUND IN PLASMA (%)	CLEARANCE (mL/min/kg)	VOL. DIST. (L/kg)	HALF-LIFE (hours)	PEAK TIME (hours)	PEAK CONCENTRATION
Venlafaxine, ^a Desvenlafaxine ^b							
10-45	V: 4.6 ± 3.0 ODV: 29 ± 7 ^c	V: 27 ± 2 ODV: 30 ± 12 ^c	22 ± 10 ^d ↔ Aged, Fem ↓ LD, RD	7.5 ± 3.7 ^d ↔ Aged, Fem, LD, RD	4.9 ± 2.4 10.3 ± 4.3 ^c ↔ Aged, Fem ↑ LD, RD	V: 2.0 ± 0.4 ODV: 2.8 ± 0.8 ^c	V: 167 ± 55 ng/mL ^e ODV: 397 ± 81 ng/mL ^e
^a Venlafaxine (V) is available as a racemic mixture; antidepressant activity resides with the <i>l</i> -(−)-enantiomer and its equipotent <i>O</i> -desmethyl metabolite (formation catalyzed by CYP2D6—polymorphic). Parameters for the derived <i>O</i> -desmethylvenlafaxine (ODV) are included. ^b <i>O</i> -Desmethyl metabolite is marketed as desvenlafaxine in an extended-release formulation as a successor to V. It has a higher oral bioavailability (80%), with a <i>T</i> _{max} of 7.5 hours. Desvenlafaxine has a much lower <i>CL</i> (3.5 mL/min/kg) and a smaller <i>V</i> _{ss} (3.4 L/kg). Its reported <i>t</i> _{1/2} matches that observed for metabolite derived from V. ^c Values for ODV after				V dosing. ^d <i>CL/F</i> and <i>V</i> _{ss} / <i>F</i> reported. ^e Mean data for V and ODV, following a 75-mg oral dose (immediate-release tablet) given three times daily for 3 days to healthy adults. <i>T</i> _{max} for an extended-release formulation is 5.5 (V) and 9 (DV) hours. <i>References:</i> Klamerus KJ, et al. Introduction of a composite parameter to the pharmacokinetics of venlafaxine and its active <i>O</i> -desmethyl metabolite. <i>J Clin Pharmacol</i> , 1992 , 32:716–724. <i>PDR54</i> , 2000 , p. 3237.			
Verapamil ^{a,b}							
Oral: 22 ± 8 SL: 35 ± 13 ↑ Cirr ↔ RD	<3	90 ± 2 ↑ Cirr ↔ RD, Atr Fib, Aged	15 ± 6 ^{c,d} ↑ Cirr, Aged, Obes ↑, ↔ Atr Fib ↔ RD, Child	5.0 ± 2.1 ↑ Cirr ↑, ↔ Atr Fib ↔ RD, Aged, Obes	4.0 ± 1.5 ^c ↑ Cirr, Aged, Obes ↑, ↔ Atr Fib ↔ RD, Child	IR: 1.1 ^e XR: 5.6-7.7 ^e	IR: 272 ng/mL ^e XR: 118-165 ng/mL ^e
^a Racemic mixture; (−)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (−)-verapamil because of a lower <i>CL</i> (10 ± 2 versus 18 ± 3 mL/min/kg). Relative concentration of the enantiomers changes as a function of route of administration. ^b Active metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), AUC is equivalent to that of parent drug (<i>t</i> _{1/2} = 9 ± 3 hours). ^c Multiple dosing causes a greater than 2-fold decrease in <i>CL/F</i> and prolongation of <i>t</i> _{1/2} in some studies, but no change of <i>t</i> _{1/2} in others. ^d Verapamil is a substrate for CYP3A4, CYP2C9, and other CYPs. ^e Mean data following a 120-mg oral conventional tablet (IR) given twice daily or range of data following a 240-mg oral extended-release (XR) dose given once				daily, both for 7-10 days to healthy adults. <i>EC</i> ₅₀ for prolongation of P-R interval after an oral dose of racemate is 120 ± 20 ng/mL; the value for IV administration is 40 ± 25 ng/mL. After oral administration, racemate concentrations >100 ng/mL cause >25% reduction in heart rate in Atr Fib, >10% prolongation of P-R interval, and >50% increase in duration of exercise in angina patients. A level of 120 ± 40 ng/mL (after IV administration) was found to terminate reentrant supraventricular tachycardias. <i>Reference:</i> McTavish D, et al. Verapamil. An updated review of its pharmacodynamic and pharmacokinetic properties, and therapeutic use in hypertension. <i>Drugs</i> , 1989 , 38:19–76.			

Vincristine ^a							
—	10-20	Low	4.92 ± 3.01 L/hr/m ² ↑ LD ^b ↔ Child	96.9 ± 55.7 L/m ² ^c	22.6 ± 16.7 ^c ↑ LD ^b	—	~250-425 nM ^d
^a Data from adult male and female cancer patients. Metabolized by CYP3A and excreted unchanged into bile (substrate for P-glycoprotein). ^b CL reduced, cholestatic liver disease. ^c t _{1/2} and V _z for terminal phase. Longer t _{1/2} (~85 ± 69 hours) also reported. ^d Following a 2-mg IV bolus dose.				<i>Surv</i> , 1993 , 17:269–281. Sethi VS, et al. Pharmacokinetics of vincristine sulfate in adult cancer patients. <i>Cancer Res</i> , 1981 , 41:3551–3555. Sethi VS, et al.  potencies
 at human transporters for monamine neurotransmitters, 406*t*
 at neurotransmitter receptors, 410*t*
 Amlodipine, 761
 absorption, fate, and excretion of, 765
 for angina, 766–767
 as antihypertensive agent, 774*t*
 cardiovascular pharmacology of, 762*t*
 pharmacokinetics of, 1813*t*
 pharmacology of, 764
 structure of, 762*t*
 therapeutic uses of, 767
 AMN107 (nilotinib), 1732
 Amobarbital, structure of, 470*t*
 Amodiaquine, 1396–1397
 Amonafide, 138*t*
 polymorphisms and response to, 159*t*
 Amoxapine
 disposition of, 409*t*
 dose and dosage forms of, 400*t*
 potencies
 at human transporters for monamine neurotransmitters, 406*t*
 at neurotransmitter receptors, 410*t*
 side effects of, 400*t*
 Amoxicillin, 1489–1490
 antimicrobial activity of, 1483
 chemistry of, 1479*t*
 pharmacokinetics of, 1814*t*
 properties of, 1479*t*
 AMP. *See* Adenosine monophosphate (AMP)
 Amperozide, potencies at neurotransmitter receptors, 427*t*
 Amphetamines
 addiction, 663
 adrenergic receptors and, 206*t*
 analgesic effect of, 298
 appetite and, 298
 cardiovascular effects of, 297
 central nervous system and, 298
 dependence and tolerance to, 299
 fatigue and, 298
 mechanism of action of, 298

 respiration and, 298
 sleep and, 298
 smooth muscles and, 297
 structure of, 279*t*
 therapeutic uses of, 299
 toxicity and adverse effects of, 298–299
 Amphotericin B
 antifungal activity of, 1571–1575
 antiprotozoal effects, 1424
 pharmacokinetics of, 1814*t*
 therapeutic uses of, 1424
 Ampicillin, 1489–1490
 antimicrobial activity of, 1483
 chemistry of, 1479*t*
 properties of, 1479*t*
 Ampiroxicam, 990
 Amplification, receptors and, 52
 Amprenavir, 1626*t*
 Amrinone, side effects of, 138*t*
 Amyl nitrite, history of, 753
 Amyotrophic lateral sclerosis (ALS)
 clinical features and pathology of, 624
 etiology of, 624–625
 treatment of, 625–626
 Amyotrophic lateral sclerosis (ALS), SLC transporters and, 102*t*
 ANADIN ULTRA (ibuprofen), 988
 Anaerobic bacteria, penicillin for, 1486
 Anakinra, 994*t*
 Analgesia/analgesics
 administration of, 516–518
 intraspinal, 500*t*

- Analgesia/analgesics (Cont.):**
 as anesthetic adjuncts, 553–554
 arrhythmias caused by, 832
 inhalation of, 518
 iontophoretic administration of, 518
 nonsteroidal, classification of, 966*t*–970*t*
 oral transucosal administration of, 518
 patient-controlled, 516
 rectal administration of, 518
 spinal delivery, 516–518
 transnasal administration of, 518
 for urinary tract infections, 1474–1475
- Analgesic nephropathy**, 975
- Anandamide**, 941
- Anaphylactic reactions**, 76
- Anaphylaxis**
 H₁ receptor antagonists and, 919
 treatment of, 920
- Anastrozole**, 1668*t*–1670*t*
 absorption, 1761
 adverse effects and toxicity of, 1762
 excretion, 1761
 for fertility induction, 1845
 mechanism of action of, 1761
 metabolism of, 127
 pharmacokinetics of, 1761, 1814*t*
 structure of, 1760*f*
 therapeutic uses of, 1757*t*, 1761
- ANCEF (cefazolin)**, 1494*t*, 1496*t*
- Ancylostoma duodenale***, 1445
- Androgen(s)**
 alkylated, 1200
 in cancer chemotherapy, 1756–1782
 physiological and pharmacological effects of, 1197–1199
 postmenopausal use, 1840
 therapeutic uses of, 1202–1203
 for Turner's syndrome, 1838
- Androgen deprivation therapy (ADT)**, 1763
 adverse effects and side effects of, 1763
 duration of response to, 1763
- Androgenetic alopecia**, drugs for, 1829–1830
- Androgen receptor antagonists**, 1205
- Androgens**, 1668*t*–1670*t*
- Androstenedione**, 1766–1767
 structure of, 1760*f*
- Androstenedione analogs**, 1761
- ANECTINE (succinylcholine chloride)**, 264*t*
- Anesthesia**
 adjuncts to, 552–554
 alpha-adrenergic agonists as adjunct, 553
 benzodiazepines as adjuncts to, 552–553
 cytoprotection with, 554–555
 general, 531–555
 actions and mechanisms of, 533–536
 anatomic sites of action, 536
 anesthetic state, 533
 cellular mechanism of, 534–535
 hemodynamic effects of, 532
 hypothermia in, 532
 molecular action of, 535–536
 nausea and vomiting after, 532–533
 potency measurement, 533–534
 principles of, 532–533
 respiratory effects of, 532
 history of, 531
 infiltration, 576
 inhalational, 544–562
 desflurane, 549–550
 enflurane, 548–549
 halothane, 545–547
 isoflurane, 547–548
 nitrous oxide, 551–552
 pharmacokinetic principles of, 544–545
 sevoflurane, 550–551
 xenon, 552
 local
 chemistry of, 559
 clinical uses of, 575–581
 differential sensitivity to, 567–569
 frequency-dependence of, 567
 H₁ receptor antagonists as, 920
 hypersensitivity to, 571–572
 low solubility, 574
 mechanism of action of, 565–567
 metabolism of, 572
 for mucous membranes, 574
 for ophthalmological use, 574
 pH and, 569–570
 for skin, 574
 undesired effects of, 571
 vasoconstrictors and, 570–571
 voltage-dependence of, 567
 muscarinic antagonists and, 234
 neuromuscular blocking agents as adjunct to, 554
- Anesthesia (Cont.):**
 parenteral, 537–539
 barbiturates, 539–540
 etomidate, 542
 ketamine, 542–543
 pharmacokinetic principles of, 537
 pharmacological properties of, 538*t*, 544*t*
 propofol, 540–542
 specific agents, 539–544
 topical, 575–576
 toxicity, 554–555
 Anesthetic(s), topical, for pruritus, 1828*t*
- Anesthetic adjuvants**, 523
- Anesthetics**, polymorphisms and response to, 160*t*
- ANGELIQ (estradiol/drospirone)**, 1839*t*
- Angina pectoris**, 751–752. *See also* Myocardial ischemia
 with arrhythmias, recommended treatment for, 769*t*

 goals, 832
 verapamil, 824*t*, 830, 831, 836*t*
 vernakalant, 845
- Antibacterial agents, for neoplastic
 disease, 1668*t*–1670*t*
 Antibiotic(s). *See also* Antimicrobial
 agents
 ABC transporters and, 105*t*, 106*t*
 arrhythmias caused by, 832
- Antibiotic(s) (*Cont.*):
 and benzoyl peroxide, combinations,
 for acne, 1817
 for cancer, 1712–1715
 histamine and, 914
 for inflammatory bowel disease,
 1360
 and statins, interactions, 896
 systemic
 for acne, 1816–1817
 for cutaneous infections, 1816
 therapeutic uses of, for
 inflammatory bowel disease,
 1352*t*
 topical, for acne, 1816–1817
 Anticancer drugs, polymorphisms and
 response to, 159*t*
 Anticholinergic agents, 211–212
 anticholinesterase for intoxication
 with, 252
 for bowel disorders, 1340–1341
 for nausea and vomiting, 1344
 Anticholinergic toxidrome, 83*t*
 Anticholinergic toxidrome antidote,
 86*t*
 Anticholinesterase agents
 absorption of, 247
 acetylcholinesterase structure and,
 240–241
 acute intoxication by, 248
 “aging” of, 249
 for Alzheimer’s disease, 252–253
 for anticholinergic intoxication, 252
 chemistry of, 242–245
 cholinesterase reactivators and, 249
 definition of, 239
 disposition of, 249
 effector organ action, 242
 excretion of, 247
 eye and, 246, 250–251
 gastrointestinal tract and, 246
 for glaucoma, 250–251
 heart and, 246–247
 history of, 239
 mechanism of action of, 241–242
 for myasthenia gravis, 251–252
 neuromuscular junction and, 246
 noncovalent, 242
 for paralytic ileus, 250
 pharmacological properties of,
 245–247
 as prophylaxis for cholinesterase
 poisoning, 252
 “reversible” carbamate inhibitors,
 242

- Anticholinesterase agents (*Cont.*):
 secretory glands and, 246
 structure-activity relationships, 242–245
 therapeutic uses of, 250–253
 toxicology of, 247–250
 treatment of intoxication by, 248–249
- Anticholinesterase poisoning, 234
- Anticoagulants, 849
 antithrombin (recombinant), 860
 argatroban, 860
 bivalirudin, 859–860
 clinical use and monitoring of, 865
 desirudin, 859
 drotrecogin alfa, 860
 oral
 decreased effect of, causes, 863–864
 drug interactions with, 863–864
 mechanism of action of, 860–862
 new, 865–866
 parenteral, 853–860
- Anticonvulsants, for mania, 444–445
- Antidepressants, 398–413
 adverse effects of, 410–413
 amine effects of, 400*t*–403*t*
 atypical, disposition of, 409*t*
 clinical considerations with, 399, 405
 disposition of, 409*t*
 dosage of, 400*t*–403*t*
 drug interactions with, 412
 mechanism of action of, 398–399
 norepinephrine-selective, potencies, at human transporters for monamine neurotransmitters, 406*t*
 polymorphisms and response to, 159*t*, 160*t*
 potencies
 at human transporters for monamine neurotransmitters, 406*t*
 at neurotransmitter receptors, 410*t*
 serotonin-selective, potencies, at human transporters for monamine neurotransmitters, 406*t*
 side effects of, 400*t*–403*t*
 ultra-rapid pharmacokinetics of, 157
- Antidiuretic hormone (ADH), opioids and, 495

- Benzodiazepine-receptor agonists, novel, 467–469
- Benzodiazepines
absorption, fate, and excretion of, 463–465
addiction to, 656–657
adverse psychological effects, 465
as anesthetic adjunct, 552–553
antidote for, 86*t*
as antiepileptics, 598–599
central nervous system and, 460
chemistry of, 458, 459*t*
for nausea and vomiting, 1345–1346
pharmacological properties of, 458–465
for pruritus, 1828*t*
sleep and, 460–461
therapeutic uses of, 465–467, 466*t*
tolerance to, 460
- Benzoic acid, 1589
- Benzothiadiazides, 686
- Benzothiadiazines (thiazide diuretics),
as antihypertensive agents, 775–777
- Benzothiazepines, 102*t*
- Benzothiazipines, 761
- Benzoyl peroxide, for acne, 1817
interactions with tretinoin, 1810
- Benzphetamine, structure of, 279*t*

- Benzotropine, as antidote, 86*t*
 Benzotropine mesylate, for parkinsonism, 234
 Benzyl alcohol, for lice, 1819
 Bepotastine, for ophthalmic use, 1789
 BEPREVE (bepotastine), 1789
 Bepidil, antiarrhythmic use of, 830
 Berberine, 1339
 Besifloxacin, for ophthalmic use, 1781*t*
 BESIVANCE (besifloxacin), 1781*t*
 Beta adrenergic agonists, 289–294
 hypoglycemia and, 1248*t*
 long-acting β_2 , 293–294
 for prevention of preterm labor, 1848
 for respiratory disease, 1035–1040
 selective β_2 , 290–291
 for prevention of preterm labor, 1848
 short acting β_2 , 291–293
 Beta adrenergic antagonist antidote, 86*t*
 Beta adrenergic receptor(s), and renin release, 722, 723*f*, 724
 Beta adrenergic receptor agonists
 cardioprotective effects of, 767
 mechanism of action of, 767
 Beta adrenergic receptor agonists,
 therapeutic uses of, for heart failure, 804–805
 Beta adrenergic receptor antagonists, 310–316
 adverse effects and side effects of, 779, 831
 adverse effects of, 316–317
 as antianginal agents, 752, 768
 antiarrhythmic use of, 824*t*, 828, 831–832
 as antihypertensive agents, 774*t*
 arrhythmias caused by, 821*t*
 for cardiovascular diseases, 317–319
 cardiovascular system and, 313–314, 316
 central nervous system and, 317
 chemistry and structures of, 310
 contraindications to, 833*t*
 drug interactions with, 317
 effects on renin-angiotensin system, 746*t*
 electrophysiological actions of, 829*t*
 for glaucoma, 319, 1787
 for heart failure, 317–318
 hemodynamic effects of, with long-term administration, 774*t*
 Beta adrenergic receptor antagonists
 (*Cont.*):
 history of, 310
 for hypertension, 314–315
 hypoglycemia and, 1248*t*
 mechanism of action of, in heart failure, 800–801
 metabolic effects of, 315
 in myocardial infarction, 317
 nonselective, 320, 326, 1787
 overdosage, 317
 pharmacological properties of, 312–316
 precautions with, 779
 pulmonary system and, 315, 316–317
 selection of, 319–320
 selective, 1787
 therapeutic uses of, 317–320, 767–768
 for heart failure, 800–801
 for myocardial infarction, 768
 for myocardial ischemia, 767–768
 with calcium channel blockers, 768, 770
 combination therapy, 768
 with nitrates, 768–770
 for unstable angina, 768
 third-generation, 328–330
 withdrawal, arrhythmias caused by, 821*t*
 Beta adrenergic receptors, 201, 205–207
 β_2 , histamine and, 914
 functions of, 205
 intracellular signaling pathways, 205
 physiological basis of function of, 281–282
 polymorphisms, 160*t*
 subtypes, 204*t*
 Beta blockers, polymorphisms and response to, 159*t*, 160*t*
 BETADINE (povidone iodine), 1790
 Betamethasone, relative potencies and equivalent doses of, 1216*t*
 Betamethasone dipropionate
 cream, 1225*t*
 lotion, 1225*t*
 ointment, 1225*t*
 Betamethasone valerate
 cream, 1225*t*
 lotion, 1225*t*
 ointment, 1225*t*
 BETAPACE (sotalol), 845
 BETATREX (betamethasone valerate ointment), 1225*t*
 Betaxolol, 312*f*
 absorption, fate, and excretion of, 328
 as antihypertensive agent, 774*t*
 for ophthalmic use, 1787
 therapeutic uses of, 328
 Bethanechol
 actions of, 222
 cholinergic receptors and, 206*t*
 gastrointestinal tract and, 224
 pharmacological properties of, 223*t*
 structure of, 222*f*
 therapeutic use of, 224
 urinary tract and, 224
 Betrixaban, 866
 Bevacizumab, 1738, 1739, 1745, 1746*t*
 clinical pharmacology, 1739
 dosage and administration of, 1747*t*
 for retinal neovascularization and macular degeneration, 1794
 toxicity of, 1739–1740, 1747*t*
 Bexarotene, 1809, 1810*t*, , 1811*t*
 1811–1812
 adverse effects and side effects of, 1812
 for cutaneous T-cell lymphoma, 1811, 1812
 drug interactions with, 1812
 formulation, 1810*t*
 irritancy, 1810*t*
 mechanism of action of, 1812
 pregnancy category, 1810*t*
 receptor specificity, 1810*t*, 1811*t*
 structure of, 1810*t*, 1811*t*
 systemic
 pharmacokinetics of, 1811*t*
 standard dosing range, 1811*t*
 BEXXAR (iodine-131 tositumomab), 1749
 Bezafibrate
 adverse effects of, 902–903
 chemistry of, 901
 and lipoproteins, 902
 mechanism of action of, 902
 structure of, 901*f*
 BG9179, therapeutic uses of, 793
 Bicalutamide, 1205, 1765–1766
 pharmacokinetics of, 1817*t*
 structure of, 1761*f*
 BICNU (carmustine), 1821
 BIDIL (hydralazine), 795
 Biguanides, 91–92
 Bile acid binding resins, 1266

- Bile acids, 1346–1347
 Bile acid sequestrant agents, 1336–1337
 Bile-acid sequestrants, 898–899
 adverse effects of, 899
 chemistry of, 898–899
 drug interactions with, 899
 and lipoprotein levels, 899
 mechanism of action of, 899
 structures of, 898^f
 therapeutic uses of, 899
 Bile acid synthesis, 127
 Bile salt export pump (BSEP), 93, 107
 Bile salt malabsorption, primary, 102^t
 Bile salts, ABC transporters and, 105^t
 Biliary excretion, 26
 Biliary tract
 muscarinic antagonists and, 229
 opioids and, 498
 Bilirubin monoglucuronide, 105^t
 Bimatoprost, 952
 for glaucoma, 1787
 nor-Binaltorphimine, actions and
 selectivities of, 485^t
 Bioavailability
 absorption *vs.*, 19
 of common drugs, 1809^t–1890^t
 definition of, 19
 disposition and, 28
 extent of, 33–34
 factors influencing, 20
 first-pass effect and, 19–20
 hepatic disease and, 1802
 in parenteral administration, 20
 as pharmacodynamic parameter,
 1802
 rate of, 33–34
 Biocompatible polymers, 23
 Bioequivalence, 23
 Biological agents
 classes, 1824
 in dermatology, 1824–1827, 1825^t
 for inflammatory bowel disease,
 1359–1360
 for psoriasis, 1824
 mechanism of action of, 1826^f
 Biological induction therapy,
 1006–1007
 Biological License Application (BLA),
 79
 Biological response modifier(s), in
 cancer treatment, 1745–1750
 Biological response modifiers
 for inflammatory bowel disease,
 1352^t
 for neoplastic disease, 1668^t–1670^t
 Biological toxins, 575
 Biotransformation, in liver, 27
 Biperiden, 234
 Bipolar (manic-depressive) disorder
 lithium for, 447
 prophylactic treatment of, 448
 Birth defects, oral anticoagulant-
 induced, 864
 Bishydroxycoumarin, 860
 Bismuth compounds, 1337
 Bisotrizole, 1827
 Bisoprolol, 312^f, 327–328
 as antihypertensive agent, 774^t
 Bisphosphonates, 1294–1296
 absorption of, 1296
 adverse effects of, 1296
 excretion of, 1296
 for osteoporosis, 1299
 Bitolterol, 292^f, 293
 Bivalirudin, 859–860
 therapeutic uses of, in myocardial
 ischemia, 771
 BLA. *See* Biological License
 Application (BLA)
 “Black box,” 9
 Bladder, urinary
 ABC transporters in, 106^t
 acetylcholine and, 221–222
 atony, anticholinesterase agents for,
 250
 in autonomic nervous system, 179^t
 bethanechol and, 224
 choline esters and, 223^t
 muscarinic antagonists and, 231
 opioids and, 497
 Bladder cancer, drugs for, 1668^t–1670^t
 BLENOXANE (bleomycin), 1823
 Bleomycin(s), 1668^t–1670^t
 for cancer, 1716–1718
 intralesional
 adverse effects and side effects of,
 1823
 for squamous cell carcinoma,
 1823
 for warts, 1823
 mechanism of action of, 1820^t
 systemic, for Kaposi sarcoma, 1823
 Blepharitis
 fungal, 1784^t
 yeast, 1784^t
 Blepharoconjunctivitis, bacterial,
 treatment of, 1781^t
 Blinking, 1773
 Blistering diseases, autoimmune, 1816
 mycophenolate mofetil for, 1823
 Blood-cerebrospinal fluid barrier,
 intrathecal injection and, 22
 Blood-brain barrier (BBB), 365–366
 ABC transporters and, 104
 distribution of drugs and, 25
 intrathecal injection and, 22
 transporters and, 91–93, 116
 vectorial transport in, 96^f
 Blood-cerebrospinal fluid barrier
 intrathecal injection and, 22
 transporters and, 116
 Blood circulation, muscarinic
 antagonists and, 228
 Blood dyscrasias, androgens for, 1204
 Blood pressure
 angiotensin II and, 727^f, 730
 epinephrine and, 282–283
 kinins and, 931
 normal, in adults, 773^t
 pharmacological lowering of, effects
 on RAS, 746^t, 747
 regulation, role of kidneys and fluids
 and electrolytes, 698^f
 Blood vessels
 alpha adrenergic receptors in, 203^t
 in autonomic nervous system, 178^t
 BMS-354825 (dasatinib), 1732
 Body temperature
 ethanol and, 637
 muscarinic antagonists and,
 229–230
 opioids and, 498
 Bolus injection, 22
 Bone
 disorders of, 1286–1290
 distribution in, 24–25
 eicosanoids and, 951
 infections of, quinolones for, 1473
 mass, 1285
 parathyroid hormone and, 1279
 physiology, 1285–1286
 remodeling, 1285–1286
 skeletal organization and, 1285
 Bone marrow, alkylating agents and,
 1681
 Bone mineral, mobilization of, vitamin
 D and, 1283
 Bone mineral density (BMD)
 bone physiology and, 1285
 postmenopausal, estrogens and,
 1838
 Bortezomib, 1742–1743
 absorption, 1743
 chemistry, 1742
 elimination, 1743

- Bortezomib (Cont.):**
 mechanism of action of, 1743
 pharmacokinetics of, 1743
 structure of, 1743
 therapeutic uses of, 1743
 toxicity of, 1743
- Bosentan**, 110
- Botulinum toxin**
 adverse effects and side effects of, 1792
 cholinergic receptors and, 206*t*
- Bowel irrigation**, 84–85
- Bowen's disease**
 5-fluorouracil for, 1821
 imiquimod for, 1823
- Bowman's membrane**, 1774–1775
- Bradycardia**
 atropine for, 233
 differential diagnosis of, in toxicity, 83*t*
- Bradykinin**, 911, 926–932, 927*f*
 antagonists, 932
 degradation, 930*f*
 [des-Arg⁹]-, structure of, 928*t*
 history of, 926
 and inflammation, 931, 960
 pain and, 930–931
 as pruritogen, 1815
 structure of, 928*t*
 therapeutic uses of, potential, 926
- Bradykinin receptor(s)**, 926, 929–930
- Brain**
 cellular organization of, 364
 drug action in, transporters and, 115–116
 microanatomy of, 364–366
- Brain natriuretic peptide (BNP)**, 695–696
- Brainstem**, 364
 alpha adrenergic receptors in, 203*t*
 beta adrenergic receptors in, 204*t*
- Brain tumor**, drugs for, 1668*t*–1670*t*
- Bran**, constipation and, 1331
- Brater's algorithm**, for diuretic therapy, 699, 700*f*
- Breast**, progestins and, 1182
- Breast cancer**
 drugs for, 1668*t*–1670*t*
 ER+, anti-estrogen therapy for, 1756–1760, 1757*t*
 HER2/neu-overexpressing, 1737
 metastatic, 1755–1756
 risk, oral contraceptives and, 1834
 tamoxifen for, 1179
- Breast cancer (Cont.):**
 treatment
 androgens in, 1756
 estrogens in, 1756
- Breast cancer resistance protein (BCRP)**, 107, 116
- Breast milk**, drugs in, 1847
- Bremazocine**, actions and selectivities, 485*t*
- BRETHINE (terbutaline)**, 1848
- Bretylum**
 adrenergic receptors and, 206*t*
 antiarrhythmic use of, 837
 contraindications to, 833*t*
- BRETYLOL (bretylum tosylate)**, 837
- BREVIBLOC (esmolol)**, 840
- BREVICON (ethinyl estradiol/norethindrone)**, 1835*t*
- BRILINTA (ticagrelor)**, 871–872
- Brimonidine**, 297
 for ophthalmic use, 1787
- Brinzolamide**, 680
 for ophthalmic use, 1787
- Broad Institute Software**, 153*t*
- Bromfenac**, for ophthalmic use, 1789
- Bromocriptine**, 1114
 as antidote, 86*t*
 dosage of, 614*t*
 hypoglycemia and, 1248*t*
 therapeutic use of, for parkinsonism, 614*t*
- BROMPHEN (brompheniramine maleate)**, 921*t*
- Brompheniramine maleate**, 921*t*
- Bronchial muscle**, eicosanoids and, 950
- Bronchodilators**, 1035
 arrhythmias caused by, 832
 novel classes of, 1046
- Bronchomotor tone**, acetylcholine and, 221
- Bronchospasm**
 angina pectoris with, recommended treatment for, 769*t*
 histamine and, 917–918
- Brotizolam**, structure of, 459*t*
- BRUFEN (ibuprofen)**, 988
- Brugia malayi*, 1446
- Brugia timori*, 1446
- BSEP. See** Bile salt export pump (BSEP)
- BuChE. See** Butyrylcholinesterase (BuChE)
- Bucindolol**, 312*f*, 329
- Bulk-flow transfer**, limitations of, 17
- Bulk-forming agents**, 1336
- Bullous disease(s)**, autoimmune, IVIG for, 1827
- Bullous pemphigoid**
 azathioprine for, 1820–1821
 cyclophosphamide for, 1821
 cyclosporine for, 1821
 dapsone for, 1823
 glucocorticoids for, 1809
 mycophenolate mofetil for, 1823
- Bumetanide**, 682–684
 as antihypertensive agent, 774*t*, 777
 for heart failure, 790–791
 pharmacology of, 683*t*
 structure of, 683*t*
- BUMEX (bumetanide)**, 682–684, 683*t*, 790–791
- Bunazosin**, 310
- Bupivacaine**, as anesthetic, 573
- Buprenorphine**
 actions and selectivities of, 485*t*
 dependence on, 512
 pharmacokinetics of, 1817*t*
 pharmacological actions of, 512
 side effects of, 512
 therapeutic uses of, 512–513
- Bupropion**
 adverse effects of, 411
 disposition of, 409*t*
 dose and dosage forms of, 402*t*
 drug interactions with, 412
 mechanism of action, 407
 pharmacokinetics of, 1817*t*
 potencies
 at human transporters for monamine neurotransmitters, 406*t*
 at neurotransmitter receptors, 410*t*
 side effects of, 402*t*
- Buserelin**, 1119*t*, 1765
 structure of, 1764*t*
- Buspirone**, 349
 pharmacokinetics of, 1818*t*
- Busulfan**, 1668*t*–1670*t*, 1685–1686
 extramedullary toxicity of, 1668*t*–1670*t*
 metabolism of, 128*t*
 pharmacokinetics of, 1818*t*
- Butabarbital**, structure of, 470*t*
- Butalbital**, 470*t*
- Butenafine**, 1589, 1817
- Butoconazole**, 1587
 for vaginal candidiasis, 1842*t*

- Butorphanol
actions and selectivities of, 485*t*
pharmacological actions of, 512
side effects of, 512
therapeutic uses of, 511–512
and vasopressin secretion, 704
- Butyrylcholinesterase (BuChE), 219, 240
- C**
- CAB. *See* Combined androgen blockade (CAB)
- Cabergoline, 1114–1115
- Cachexia, 1756
- Cadmium, 1871
- CAELYX (doxorubicin), 1823
- Cafepime, antibacterial spectrum of, 1496*t*
- Caffeine
addiction, 663
metabolism of, 128*t*
polymorphisms and response to, 159*t*
side effects of, 138*t*
- CALAN (verapamil), 763*t*, 831
- CALCIDRINE SYRUP (calcium iodide), 1153*t*
- Calcineurin inhibitors
in dermatology, 1821–1822
in immunosuppressive therapy, 1008–1012
- Calcipotriene
dosage and administration of, 1813
mechanism of action of, 1813
for psoriasis, 1813
structure of, 1813
- Calcitonin (CT)
chemistry and immunoreactivity of, 1283–1284
diagnostic uses of, 1294
history and source of, 1283
mechanism of action of, 1284
secretion of, regulation of, 1284
therapeutic uses of, 1294
- Calcitonin gene-related peptide (CGRP), 172
Calcitriol, 1277–1292, 1818*t*
- Calcium
abnormal metabolism of, 1286–1288
homeostasis, 1275–1276
hormonal regulation of, 1277–1285
hypercalcemia, 1286–1288
hypocalcemia, 1288
hypoglycemia and, 1248*t*
intestinal absorption of, 1282–1283
- Calcium (*Cont.*):
for osteoporosis, 1300
parathyroid hormone and, 1278–1280
as second messenger, 57–58
therapeutic uses of, 1291
vitamin D regulation of, 1280–1283
- Calcium channel(s), 59
in cardiomyocytes, 802*f*
- Calcium channel antagonists
ABC transporters and, 105*t*
antidote, 86*t*
hypoglycemia and, 1248*t*
polymorphisms and response to, 159*t*
toxidrome, 83*t*
- Calcium channel blockers, for
prevention of preterm labor, 1848
- Calcium-channel blockers
absorption, fate, and excretion of, 765
as antianginal agents, 752, 766–767
as antiarrhythmic agents, 767
antiarrhythmic use of, 830–831
as antihypertensive agents, 767, 774*t*, 784
cardiac electrophysiological actions of, 829*t*
cardiovascular pharmacology of, 762*t*–763*t*
chemistry of, 761, 762*t*–763*t*
drug interactions with, 766
effects on renin-angiotensin system, 746*t*
frequency dependence, 764
hemodynamic effects of, with long-term administration, 774*t*
history of, 761
mechanism of action of, 761–763
pharmacological properties of, 763–766
cardiac, 763–764
cardiovascular, 763
hemodynamic, 764–765
vascular, 763
renal effects of, 767
structures, 762*t*–763*t*
therapeutic uses of, 766–767
in myocardial ischemia, 761–767
with beta-adrenergic receptor antagonists, 768, 770
with nitrates, 770
toxicity and untoward responses to, 765–766
use dependence, 764
- Calcium channels, acetylcholine and, 221
- Calcium chloride, as antidote, 86*t*
- Calcium gluconate, 86*t*, 1291
- Calcium iodide, 1153*t*
- CALDOLOR (ibuprofen), 988
- Calicheamicin, 23
- CAMPATH (alemtuzumab), 1748
- Camptothecin analogs, 1668*t*–1670*t*, 1710–1712
- Camptothecins SN-38, ABC transporters and, 106*t*
- Canakinumab, 961
- Canaliculitis, fungal, 1783
- Canal of Schlemm, 1774, 1776*f*

 mechanism of action of, 902
 structure of, 901*f*
- Ciprofloxacin
 for chancroid, 1842*t*
 pharmacokinetics of, 1825*t*
 SLC transporters and, 102*t*
 therapeutic uses of, for
 inflammatory bowel disease,
 1352*t*
- Ciproxifan, 925
- Circulation
 carbon dioxide and, 562
 muscarinic antagonists and, 228
- Cisapride, 1326–1327
 arrhythmias caused by, 832
 effects on bowel function, 1330*t*
 polymorphisms and response to,
 161*t*
 therapeutic toxicity of, 79–80
- Cisatracurium
 characteristics of, 264*t*
 dosing of, 265*t*
 structure of, 259*f*
- Cisplatin, 1668*t*–1670*t*, 1689
 pharmacokinetics of, 1824*t*
 SLC transporters and, 103*t*
 toxicity of, extramedullary, 1682*t*
- Citalopram
 arrhythmias caused by, 832
 disposition of, 409*t*
 pharmacokinetics of, 1838*t*
 potencies
 at human transporters for
 monamine neurotransmitters,
 406*t*
 at neurotransmitter receptors, 410*t*
 nor₁-Citalopram, potencies at human
 transporters for monamine
 neurotransmitters, 406*t*
 nor₂-Citalopram, potencies at human
 transporters for monamine
 neurotransmitters, 406*t*
- Citrate, 853
- c-jun* oncogene, 730
- CL-385004, 716*t*
- Cladribine, 1668*t*–1670*t*, 1703–1704
- Cladribine, SLC transporters
 and, 102*t*
- CLAFORAN (cefotaxime), 1496*t*
- CLARINEX (desloratadine), 922*t*, 1816
- Clarithromycin
 pharmacokinetics of, 1825*t*
 polymorphisms and response to,
 161*t*
- CLARITIN (loratadine), 922*t*, 1816
- Classes of drugs, choosing within,
 1802
- Claudication, treatment of, 771–772
- Clearance, 28–30
 alterations of, to individual patient,
 1806–1807
 of common drugs, 1809*t*–1890*t*
 creatinine, 1803
 definition of, 29
 hepatic, 29–30
- Clearance (*Cont.*):
 plasma, as pharmacodynamic
 parameter, 1803–1804
 renal, 30
- Clemastine fumarate, 921*t*
- CLEOCIN-T (clindamycin), 1817
- Clevidipine
 as antihypertensive agent, 774*t*
 pharmacology of, 765
- Clevudine, 1617
- CLIMARA (estradiol), 1839*t*
- CLIMARA PRO (estradiol/levonorgestrel),
 1839*t*
- Clindamycin
 absorption of, 1535
 for bacterial vaginosis, 1842*t*
 distribution of, 1535
 excretion of, 1535
 gastrointestinal effects of, 1535
 for malaria, 1390*t*
 pharmacokinetics of, 1826*t*
 therapeutic uses of, 1535
 topical, for acne, 1817
 untoward effects of, 1535
- Clinical pharmacokinetics, 27–30
- Clinical practice, pharmacogenetics in,
 164–165
- Clinical trials, 78–79
 adverse reactions in, 10
 conduct of, 7–9
 ethical considerations in, 7
 phase I, 8*t*, 9, 79
 phase II, 8*t*, 9, 79
 phase III, 8*t*, 9, 79
 phase IV, 8*t*, 9
 surrogate end points in, 9
- CLINORIL (sulindac), 985
- Clitocybe, 225
- Clobazam, structure of, 459*t*
- Clobenpropit, 925
- Clobetasol propionate
 cream, 1225*t*
 ointment, 1225*t*
- Clofarabine, 1704
- Clofazimine, 1559
- Clofibrate
 adverse effects of, 902–903
 chemistry of, 901
 history of, 901
 hypoglycemia and, 1248*t*
 metabolism of, 128*t*
 and statins, combination therapy
 with, 898
 structure of, 901*f*
 therapeutic uses of, 903

- CLOMID (clomiphene citrate), 1841–1843
- Clomiphene, 1179
adverse effects and side effects of, 1843
teratogenicity of, 1843
- Clomiphene citrate, 1841–1843
- Clomipramine
disposition of, 409*t*
dose and dosage forms of, 400*t*
polymorphisms and response to, 160*t*
potencies
at human transporters for
monamine neurotransmitters, 406*t*
at neurotransmitter receptors, 410*t*
side effects of, 400*t*
- Clonazepam
administration and uses of, 466*t*
metabolism of, 128*t*
pharmacokinetics of, 1826*t*
for pruritus, 1828*t*
side effects of, 138*t*
structure of, 459*t*
- Clonidine
absorption, fate, and excretion of, 296
adrenergic receptors and, 206*t*
adverse effects and side effects of, 782
adverse effects of, 296
as antihypertensive agent, 774*t*, 781–782
arrhythmias caused by, 821*t*
hypoglycemia and, 1248*t*
for menopausal symptoms, 1840
pharmacokinetics of, 1826*t*
pharmacological properties of, 295–296
therapeutic uses of, 296–297, 782
- Clonorchis sinensis*, 1449
- Clopidogrel
antiplatelet effects, site of action, 868*f*
for myocardial ischemia, 752
pharmacokinetics of, 1827*t*
polymorphisms and response to, 159*t*
structure of, 869*f*
- Clorazepate
pharmacokinetics of, 1827*t*
structure of, 459*t*
- Clostridial infections, penicillin for, 1487
- Clostridium sordellii*
septic shock, 1837
uterine infection, 1837
- Clotrimazole, 1587, 1817
for vaginal candidiasis, 1842*t*
- Cloxacillin, 1488
chemistry of, 1479*t*
properties of, 1479*t*
- Clozapine, 350, 920
dosage of, 425*t*
metabolism of, 432*t*
pharmacokinetics of, 1827*t*
polymorphisms and response to, 160*t*
potencies at neurotransmitter receptors, 427*t*
side effects of, 425*t*
- CML. *See* Chronic myelogenous leukemia (CML)

administration and uses of, 466*t*
structure of, 459*t*
- ESTRACE (estradiol cream), 1839*t*
- ESTRACE (micronized estrogen), 1839*t*
- ESTRADERM (estradiol), 1839*t*
- Estradiol, transdermal
brand names, 1839*t*
formulations, 1839*t*
- Estradiol, ABC transporters and, 106*t*
- Estradiol-17-D-glucoronide, 105*t*
- Estramustine, 1709
- ESTRASORB (estradiol), 1839*t*
- ESTRING (estradiol ring), 1839*t*
- ESTROGEL (estradiol), 1839*t*
- Estrogen(s), 1668*t*–1670*t*
absorption, fate, and elimination of, 1173–1174
in anti-androgen therapy, 1766
biosynthesis of, 1164–1165
in cancer chemotherapy, 1756–1782
carcinogenic action of, 1174–1175
cardiovascular effects of, 1174–1175
chemistry of, 1163–1164
cognition and, 1175
conjugated, 1766
developmental actions of, 1165–1166
and dyslipidemia, 890*t*
history of, 1163
for induction of sexual maturation, 1838
mechanism of action of, 1171–1173
for menopausal symptoms, 1175–1177, 1838–1840
administration routes, 1839–1840
brand names, 1839*t*
formulations, 1839*t*
menstrual cycle and, 1166–1169
metabolic effects, 1169–1170
oral, plus progesterone
brand names, 1839*t*
formulations, 1839*t*
in oral contraceptives, 1833, 1835*t*–1836*t*
for osteoporosis, 1300
osteoporosis and, 1175–1176
physiological and pharmacological actions of, 1165–1170
therapeutic uses of, 1175–1177
transdermal, plus progesterone
brand names, 1839*t*
formulations, 1839*t*
- Estrogen(s) (*Cont.*):
untoward responses to, 1174–1175
vaginal
brand names, 1839*t*
formulations, 1839*t*
- Estrogen receptor modulators, 1177–1180
- Estrogen receptor polymorphisms, 160*t*
- Estrogen receptors, 1170–1171
- Estrogen replacement therapy, 1176–1177
polymorphisms and response to, 160*t*
- Estrogen synthesis inhibitors, 1180
- Estrone-3-sulfate, 105*t*
- ESTROSTEP (ethinyl estradiol/norethindrone), 1836*t*
- Eszopiclone, 468
pharmacokinetics of, 1839*t*
- Etanercept, 1825*t*, 1826–1827
- Ethacrynic acid, 682–684
as antihypertensive agent, 774*t*
for heart failure, 790
pharmacology of, 683*t*
structure of, 683*t*
- Ethambutol, 1558–1559
optic neuropathy caused by, 1792
pharmacokinetics of, 1839*t*
- Ethanol
absorption of, 630–631
addiction, 654–656
as antidote, 86*t*
body temperature and, 637
cardiomyopathy and, 636
cardiovascular system and, 635–636
central nervous system and, 633–635
chronic use of, 640–641
clinical uses of, 640
consumption of, 629–630
dependence on, 640–641
distribution of, 630–631
diuresis and, 637
esophagus and, 637
gastrointestinal system and, 637–638
genetic variations in metabolism of, 632
hematological effects, 639
history of, 629
hypertension and, 636
hypoglycemia and, 1248*t*
immunological effects, 639
- Ethanol (*Cont.*):
intoxication, acute, 639–640
lipoproteins and, 635–636
metabolism of, 630–631, 631*f*, 632
minerals and, 638
physiological effects of, 632–639
sexual function and, 638–639
teratogenicity of, 641–642
tolerance for, 640–641, 655
and vasopressin secretion, 704
vitamins and, 638
- Ethanolamines, 923
- Ethnic diversity, pharmacogenetics and, 150–151
- Ethinyl estradiol, 128*t*, 1668*t*–1670*t*, 1766
- Ethionamide, 1561–1562
- Ethosuximide, 596
- Ethylenediamines, 924
- Ethylenediaminetetraacetic acid (EDTA), 853, 1873–1874
- Ethylene glycol antidote, 86*t*
- Ethylenimines, 1668*t*–1670*t*
- Ethylketocyclazocine, actions and selectivities, 485*t*
- Ethylnorepinephrine, 279*t*
- Etodolac, 985–986
adverse effects, 986
compared to aspirin, 967*t*
COX isoform selectivity, 962*f*
dosage and administration of, 967*t*
pharmacokinetics of, 962*f*, 967*t*
pharmacology of, 962*f*
therapeutic uses of, 967*t*, 985
- Etomidate, 1236
as anesthesia, 542
formulations of, 538*t*
pharmacological properties of, 538*t*, 544*t*
- Etoposide, 1668*t*–1670*t*, 1715–1716
ABC transporters and, 105*t*
polymorphisms and response to, 159*t*
- Etoricoxib, 964–965, 970*t*, 992
COX isoform selectivity, 962*f*
pharmacology of, 962*f*
plasma pharmacokinetics of, 962*f*
- Etorphine, actions and selectivities, 485*t*
- Etravirine, 1641*t*, 1644
- Etretinate, 1809
pharmacokinetics of, 1811*t*
produced by acitretin and alcohol, 1812
receptor specificity, 1811*t*

- Etretinate (*Cont.*):
 standard dosing range, 1811*t*
 structure of, 1811*t*
Eubacterium lentum, and resistance to digoxin, 803
 EULEXIN (flutamide), 1668*t*–1670*t*, 1841
 EURAX (crotamiton), 1819
 EVAMIST (estradiol), 1839*t*
 Everolimus, 1013, 1743
 drug interactions with, 1744
 therapeutic uses of, 1744
 VICEL (fibrinogen glue), 1790
 EVISTA (raloxifene), 1756
 Evolution, antimicrobial resistance and, 1377–1378
 Exchangers, 95
 Excitable gap, 823*f*
 Excitation-contraction coupling, in gastrointestinal smooth muscle, 1324
 Excitatory neurotransmission, 183*f*
 Excitatory postsynaptic potential (EPSP), 184
 Excretion of drugs, 26–27
 ABC transporters in, 105*t*–106*t*
 anticholinesterase agents, 247
 biliary, 26
 epinephrine, 286
 fecal, 26
 isoprenalolol, 289
 norepinephrine, 287
 saliva and, 26–27
 unchanged urinary
 of common drugs, 1809*t*–1890*t*
 as pharmacodynamic parameter, 1802–1803
 Exemestane, 1757*t*, 1760*f*, 1762–1763
 Exenatide, 1263
 pharmacokinetics of, 1840*t*
 Exocrine glands
 H₁-receptor antagonists and, 919
 nicotine and, 271
 Exons, 148*f*
 Expectorants, 1057
 Expression regulation, of transporters, 97
 Extended-release preparations, 21
 Extent of availability, 1802
 Extracellular fluid (ECF), volume, diuretics and, 677*f*
 Extracellular fluid volume (ECFV)
 distribution of, and blood pressure regulation, 698*f*
 and edema formation, 696–698, 698*f*
 Extracorporeal photophoresis (ECP), 1814–1815
 Extramedullary toxicity, of alkylating agents, 1682*t*
 Extraneuronal sites, 189
 Eye(s)
 anatomy, physiology, and biochemistry, 1773–1778, 1776*f*
 anterior segment, 1774–1777, 1776*f*
 systemic agents affecting, 1792–1793
 anticholinesterase agents and, 246, 250–251
 autonomic innervation of, 1773, 1775*t*, 1776*f*
 in autonomic nervous system, 178*t*
 carbachol and, 224
 choline esters and, 223*t*
 eicosanoids and, 950–951
 muscarinic antagonists and, 228–229, 233
 pilocarpine and, 224
 posterior segment, 1774, 1776*f*, 1777–1778
 surface, systemic agents affecting, 1793
 systemic agents affecting, 1792–1793
 topical application of drugs to, 23
 Eyelid(s), 1773
 anatomy of, 1774*f*
 systemic agents affecting, 1793
 Ezetimibe, 903–904
 absorption, 904
 adverse effects and side effects of, 904
 combination therapy, with statins, 904
 contraindications to, 904
 drug interactions with, 904
 excretion, 904
 history of, 903
 mechanism of action of, 903–904
 pharmacokinetics of, 904, 1840*t*
 surrogate end point experiment with, 9
 therapeutic uses of, 904
F
 Facial nerve, 171, 173*f*, 174
 Facilitated diffusion, 19, 94, 94*f*
 Factor VIIa, 851
 Factor XII, 929
 Factor XIII, 851
 Factor Xa inhibitors, oral, 866
 FACTREL (gonadorelin hydrochloride), 1119*t*
 False-transmitter concept, 282
 Famciclovir, 1596*t*, 1601
 for cutaneous viral infections, 1818
 for genital herpes, 1842*t*
 for ophthalmic use, 1782, 1783*t*
 Familial Mediterranean fever, colchicine for, 996
 Familial periodic paralysis, acetazolamide for, 681
 Famotidine, 918
 arrhythmias caused by, 832
 intravenous doses of, 1313*t*
 pharmacokinetics of, 1816*t*, 1840*t*
 therapeutic uses of
 for gastroesophageal reflux disease, 1318*t*
 for ulcers, 1319*t*
 FAMVIR (famciclovir), 1596*t*, 1783*t*, 1818
 FARESTON (toremifene), 1756, 1759
 Farnesoid X receptor (FXR), 97, 140*t*
 FAS. *See* Fetal alcohol syndrome (FAS)
 Fasciculins, 241
Fasciola hepatica, 1449
Fasciolopsis buski, 1449
 FASLODEX (fulvestrant), 1756, 1759–1760
 Fat, as reservoir, 24
 FDA. *See* Food and Drug Administration (FDA)
 Febrile convulsions, 605
 Febuxostat
 absorption, 998
 adverse effects and side effects of, 998
 chemistry, 997
 distribution of, 998
 drug interactions with, 998
 elimination, 998
 mechanism of action of, 997–998
 pharmacokinetics of, 998
 structure of, 997
 therapeutic uses of, 998
 Fecal excretion, 26
 Felbamate, 601–602
 FELDENE (piroxicam), 989–990
 Felodipine, 761
 absorption, fate, and excretion of, 765
 as antihypertensive agent, 774*t*

- Felodipine (*Cont.*):
 cardiovascular pharmacology of, 762*t*
 pharmacokinetics of, 1841*t*
 pharmacology of, 764
 structure of, 762*t*
 therapeutic uses of, 767
- Female hypogonadism, 1203
- FEMARA (letrozole), 1845
- FEMCON (ethinyl estradiol/norethindrone), 1835*t*
- FEMHRT (ethinyl estradiol/norethindrone), 1839*t*
- FEMRING (estradiol ring), 1839*t*
- FEMTRACE (estradiol), 1839*t*
- Fenamates, 989
 classification of, 968*t*
- Fenofibrate
 absorption, fate, and excretion of, 902
 adverse effects of, 902–903
 chemistry of, 901
 and lipoproteins, 902
 mechanism of action of, 902
 pharmacokinetics of, 1841*t*
 and statins, combination therapy with, 898
 structure of, 901*f*
 therapeutic uses of, 903
- Fenoldopam, as antihypertensive agent, 774*t*
- Fenoprofen, 989
 compared to aspirin, 969*t*
 COX isoform selectivity, 962*f*
 dosage and administration of, 969*t*
 pharmacokinetics of, 969*t*
 pharmacology of, 962*f*
 plasma pharmacokinetics of, 962*f*
 structure of, 988*f*
 therapeutic uses of, 969*t*
- Fenoterol, 292*f*, 293
- Fentanyl, 507–508
 actions and selectivities of, 485*t*
 dosage of, 500*t*
 pharmacokinetics of, 1841*t*
 structure of, 504*f*
- Fertility induction, 1841–1845
- Ferrous sulphate, 1082
- Fesoterodine
 dosing of, 232*t*
 for overactive bladder, 231
- Fetal alcohol syndrome (FAS), 641–642
- Fetal circulatory system, NSAIDs and, 971
- Fetus
 placental transfer of drugs and, 25
 plasma pH in, 25
- Fever, 961–962
 NSAIDs and, 961–962
 NSAIDs for, 971
 warfarin-induced, 864
- Fexofenadine hydrochloride, 920, 922*t*, 924, 1816
- ABC transporters and, 105*t*
 hepatic transporters and, 110
 pharmacokinetics of, 1816*t*
- FGF. *See* Fibroblast growth factor (FGF)
- Fiber, dietary
 constipation and, 1330–1331
 effects on bowel function, 1330*t*
- Fibrates
 and plasma chylomicrons, 881
 and statins
 combination therapy with, 898
 interactions, 896
- Fibric acid derivatives, 901–903
 absorption, fate, and excretion of, 902
 adverse effects and drug interactions with, 902–903
 chemistry of, 901
 contraindications to, 902, 903
 and gallstones, 903
 history of, 901
 and lipoprotein levels, 902
 mechanism of action of, 902
 and statins, combination therapy with, 903
 structures of, 901*f*
 therapeutic uses of, 903
- Fibrinolysis, 849–853, 851*f*
 inhibitors of, 867–868
- Fibrinolytic agents, 849
- Fibrinolytic therapy, contraindications to, 867, 867*t*
- Fibroblast growth factor 23, 1285, 1738
- Fick's first law, 93
- Field block anesthesia, 576
- "Fight or flight," 180
- Filaggrin, 1803–1804, 1805*f*
- Filgrastim, 1745, 1074–1075
- FINACEA (azelaic acid), 1830
- Finasteride, 1205
 adverse effects and side effects of, 1830
- Finasteride (*Cont.*):
 for androgenetic alopecia, 1829–1830
 mechanism of action of, 1829, 1841
 pharmacokinetics of, 1842*t*
 structure of, 1829
 teratogenicity of, 1830
 therapeutic uses of, 1841
- FIRMAGON (degarelix), 1764*t*
- First-pass effect, 19–20
- FK506. *See* Tacrolimus
- FKBP12, 772
- FLAGYL (metronidazole), 23
- Flare, H₁ receptor antagonists and, 919
- Flatulence, 1347
- Flatworm infections, 1447–1448
- Flavin-containing monooxygenases (FMO), 125, 125*t*, 130
- Flavoxate hydrochloride, 232
- Flecainide
 adverse effects of, 840
 antiarrhythmic use of, 824*t*, 828, 835*t*, 840–841
 arrhythmias caused by, 821*t*
 contraindications to, 833*t*
 digoxin and, 839
 dosage of, 835*t*
 electrophysiological actions of, 829*t*
 pharmacokinetics of, 835*t*, 840–841, 1842*t*
 pharmacology of, 840
 polymorphisms and response to, 159*t*
 structure of, 840
- FLECTOR (diclofenac), 986, 987
- FLOLAN (epoprostenol), 952
- FLOLAN (prostacyclin), 952
- FLORONE (diflorasone diacetate), 1225*t*
- Floxuridine, 1668*t*–1670*t*
- Fluconazole, 1579–1580
 arrhythmias caused by, 832
 indications for, 1816*t*
 pharmacokinetics of, 1842*t*
 for vaginal candidiasis, 1842*t*
- Flucytosine, 1575–1576
- Fludarabine phosphate, 1702–1703
 pharmacokinetics of, 1842*t*
- Fludrocortisone, 755
 relative potencies and equivalent doses of, 1216*t*
- Flufenamic acid, 968*t*, 989
- Fluid balance, and blood pressure regulation, 698*f*
- Flukes, 1448–1449
- FLUMADINE (rimantadine), 1596*t*

- Flumazenil, 468–469, 1059
 as antidote, 86*t*
 structure of, 459*t*
 Fluocinolone acetonide
 cream, 1225*t*
 ointment, 1225*t*
 Fluocinonide
 cream, 1225*t*
 gel, 1225*t*
 ointment, 1225*t*
 FLUONEX (fluocinonide cream), 1225*t*
 FLUORESOF (fluorexon), 1793
 Fluorexon, 1793
 Fluoride
 absorption of, 1301
 dental caries and, 1302
 distribution of, 1301
 excretion of, 1301
 pharmacological actions of, 1301
 poisoning by, 1301–1302
 Fluoride antidote, 86*t*
 Fluoroquinolones, 1560
 5-Fluorouracil, 1668*t*–1670*t*
 in dermatology, 1821
 mechanism of action of, 1820*t*, 1821
 pharmacokinetics of, 1843*t*
 polymorphisms and response to, 159*t*
 urinary excretion of, 1843*t*
 5-Fluorouracil, polymorphisms and
 response to, 160*t*
 Fluoxetine
 arrhythmias caused by, 832
 disposition of, 409*t*
 pharmacokinetics of, 1843*t*
 polymorphisms and response to,
 159*t*, 160*t*
 potencies
 at human transporters for
 monamine neurotransmitters,
 406*t*
 at neurotransmitter receptors, 410*t*
 SLC transporters and, 102*t*
 urinary excretion of, 1843*t*
 Fluoxymesterone, 1668*t*–1670*t*
 Fluphenazine
 dosage of, 424*t*
 pharmacokinetics of, 1843*t*
 potencies at neurotransmitter
 receptors, 427*t*

 - FDA-approved indications for, 1825*t*
 - for inflammatory bowel disease, 1352*t*, 1359–1360
 - mechanism of action of, 1827
 - method of administration, 1825*t*
- Infliximab (*Cont.*):
 - pregnancy category, 1825*t*
 - for psoriasis, 1827
 - dosing, 1825*t*
 - efficacy, 1825*t*
 - structural class, 1825*t*
- Influenza, drugs for, 1605–1609
- Inhalants, abuse and addiction, 666
- Inhalational administration, 22–23, 1034–1035
- Inhalers
 - dry-powder, 1035
 - metered-dose, 1035
- Inheritance. *See* Pharmacogenetics
- Inhibition
 - competitive, 95
 - noncompetitive, 96
 - uncompetitive, 96
- Inhibitory neurotransmission, 183*f*
- Inhibitory postsynaptic potential (IPSP), 184
- Injection, parenteral, 22
- Innovation, “me too” drugs vs., 13–14
- Inocybe, 225
- Inodilator, 805
- Inosine monophosphatase
 - dehydrogenase (IMPDH), 1823
- Inosine triphosphatase (ITPA)
 - polymorphism, 161*t*
- INR. *See* International normalized ratio (INR)
- Inscription, 1879
- Insect bites, H₁ receptor antagonists for, 922
- Insecticides, 247–248
 - organophosphorus, 239
- Insertions, 147, 147*f*, 148
- Insertion sequences, 1378
- Insomnia
 - categories of, 477–478
 - conditioned (learned), 478
 - H₁-receptor antagonists for, 923
 - long-term, 477, 478
 - major psychiatric illnesses and, 477
 - management of, 477–479
 - in older patients, 478
 - short-term, 477
 - sleep state misperception, 478
 - transient, 477
- INSPIRA (eplerenone), 693*t*
- Insulin
 - absorption of, 1254
 - adverse reactions to, 1254–1255
 - analogs, 1262*f*

- Insulin (*Cont.*):
 as antidote, 86*t*
 blood levels in type 2 diabetes, 1249*f*
 continuous subcutaneous infusion of, 1253–1254
 delivery, 1253–1256
 formulations, 1249*t*
 and glucose homeostasis, 1240*f*
 and incretins, 1271*f*
 and plasma chylomicrons, 881
 preparation, 1249*t*, 1250–1251
 protamine-containing, 858–859
 receptor signaling, 1243*f*
 regimens, 1263*f*
 secretagogues, 1253*t*, 1256–1262
 secretion of, 1240–1242
 regulation of, 1242*f*
 synthesis and structure, 1241*f*
 vs. other diabetes treatments, 1259*t*
 Insulin-like growth factor 1 receptor (IGF-1R), 1744, 1744*f*
 Insulin-like growth factors (IGFs), type 1, 1117
 Insulinoma, malignant, drugs for, 1668*t*–1670*t*
 Insulin receptor(s), 1242–1244
 Insulin resistance, 877–878, 1246–1247
 Insulin sensitizer(s), effects on ovulation and fertility, 1845
 Integrase inhibitors, 1658–1659
 Integrative chemical communication, in central nervous system, 366–371
 Intellectual property, 12
 Interactions, drug-drug interactions, 77–78
 CYPs and, 129–130
 hepatic transporters and, 110
 Intercellular adhesion molecule 1 (ICAM-1), in inflammation, 960
 Interferon(s), 1596*t*
 for cutaneous viral infections, 1818
 immunostimulation and, 1022
 polymorphisms and response to, 160*t*
 Interferon alfa, 1668*t*–1670*t*
 pharmacokinetics of, 1851*t*
 Interferon beta, pharmacokinetics of, 1852*t*
 Interferon(s) (IFN), 1745
 Intergenic polymorphism, 155*t*
 Intergenic region, 148*f*
 Interleukin(s) (IL), 1070*t*, 1745
 IL-1
 as immunosuppressive agent, 1018–1019
 in inflammation, 960, 961
 in rheumatoid arthritis, 961
 IL-2, 1070*t*, 1668*t*–1670*t*, 1769–1770
 immunosuppression and, 1022
 Intermediate-density lipoproteins (IDL), 878, 879*t*
 Intermittent dosage, 36
 International HapMap Project, 153*t*
 International normalized ratio (INR), 862, 864, 865
 International sensitivity index (ISI), 865
 Interstitial cells of Cajal (ICCs), 175
 Interval, dosing, for intermittent dosage, 36
 Intestinal secretions, eicosanoids and, 950
 Intestines. *See also* Gastrointestinal tract

 in central nervous system, 367–371
 Ionic inhibitors, 1151–1152
 Ionic milieu, 51
 Iontophoretic administration, of analgesics, 518
 IOP. *See* Intraocular pressure
 Iopanoic acid, 1153*t*
 Iothalamate, 1153*t*
 Ipodate, 1153*t*
 Ipratropium, 226–227, 227*f*, 230–231
 IPRIVASK (desirudin), 859
 IPSP. *See* Inhibitory postsynaptic potential (IPSP)
 IQIUX (levofloxacin), 1781*t*
 Irbesartan, 738
 as antihypertensive agent, 774*t*, 785–786
 pharmacokinetics of, 1852*t*
 structure of, 737*f*

- Iridocyclitis, 233
viral, 1783*t*
- Irinotecan, 1668*t*–1670*t*
Gilbert's syndrome and, 133
hepatic transporters and, 110
metabolism of, 131, 131*f*
pharmacokinetics of, 1852*t*
- Iris, 1774, 1775–1776, 1776*f*
in autonomic nervous system, 178*t*
- Iron, 1076–1081
adverse effects of, 1083
environment and, 1077
history of, 1077
metabolism of, 1077–1079
parenteral, 1083–1085
poisoning, 1083
requirements and availability of, 1079–1081
- Iron antidote, 86*t*
- Iron deficiency, 1076–1086
oral iron for, 1082–1083
Iron dextran, 1084–1085
Iron sucrose, 1085
- Irritable bowel syndrome (IBS), 1339–1340
- Irritant laxatives, 1333–1334
- ISATX247, 1012
- ISATX247, 1790
- Isavuconazole, 1582
- Ischemic burden, 751
- ISI. *See* International sensitivity index (ISI)
- ISMO (isosorbide mononitrate), 794
- ISMO (isosorbide-5-mononitrate), 754*t*

 Penicillin V
 antimicrobial activity of, 1483, 1484
 chemistry of, 1479t
 oral administration of, 1484–1485
 properties of, 1479t
Penicillium citrinum, 893
 PENLAC (ciclopirox topical), 1818
 Pentamidine, 1434–1435
 arrhythmias caused by, 832
 hypoglycemia and, 1248t
 Pentazocine, 510–511
 actions and selectivities of, 485t
 Pentobarbital, 470t
 Pentostatin, 1668t–1670t, 1704–1705
 Pentoxifylline, 771–772
 Peptic ulcer(s), 1319–1321
 muscarinic antagonists and, 232–233
 NSAID-related, 1320–1321
 stress-related, 1321
 Peptides, histamine release by, 914
 Peptide YY, 213
 Percutaneous coronary intervention, 753
 Perfluorocarbons, as vitreous substitute, 1790
 Perfluoropropane gas, as vitreous substitute in surgery, 1790
 Pergolide
 dosage of, 614t
 therapeutic uses of, for parkinsonism, 614t
 Perhexiline, polymorphisms and response to, 159t
 PERIACIN (ciproheptadine hydrochloride), 921t
 Perindopril
 as antihypertensive agent, 774t, 784–785
 clinical pharmacology of, 734
 structure of, 732f
 Perioral tremor, in antipsychotic drug therapy, 437t
 Peripheral nervous system, nicotine and, 271
 Peripheral vascular disease, 877
 and dyslipidemia treatment, 890
 severe, angina pectoris with, recommended treatment for, 769t
 treatment of, 771–772
 Peritonitis, gentamicin for, 1515
 Permeability, of cell membranes, 17
 Permethrin
 mechanism of action of, 1818
 structure of, 1818
 Peroxisome proliferator activator receptor(s) (PPAR), 140, 140t, 902
 eicosanoids and, 946
 Perphenazine
 dosage of, 424t
 potencies at neurotransmitter receptors, 427t
 side effects of, 424t

 PROPINE (epinephrine), 1787
Propionibacterium acnes, 1816–1817
 Propionic acid derivatives, 987–989
 classification of, 968*t*–969*t*
 drug interactions with, 988
 mechanism of action of, 987
 structures of, 988*f*
 therapeutic uses of, 987–988
 Propionyl levocarnitine, 772
 Propofol
 in anesthesia, 540–542
 formulations of, 538*t*
 pharmacokinetics of, 1878*t*
 pharmacological properties of, 538*t*, 544*t*
 Propoxyphene
 absorption, fate, and excretion of, 509
 pharmacological actions, 509
 structure of, 504*f*
 therapeutic uses of, 510
 tolerance and dependence, 509–510
 toxicity, 509
 Propranolol, 128*t*
 absorption, fate, and excretion of, 320
 adrenergic receptors and, 207*t*
 antiarrhythmic use of, 828, 831–832, 836*t*
 as antihypertensive agent, 774*t*, 778–779
 cardioprotective effects of, 767
 dosage of, 836*t*
 electrophysiological actions of, 829*t*
 pharmacokinetics of, 29, 836*t*, 1878*t*
 polymorphisms and response to, 159*t*
 structure of, 311*f*
 therapeutic uses of, 320
N-propylalajmaline, 159*t*
 Propylene glycol, keratolytic effect of, 1829
 Propylhexedrine, structure of, 279*t*
 Propylidone, 1153*t*
 Prorenin, 722
 activation of, 724*f*
 angiotensin II-dependent and angiotensin II-independent actions of, 726*f*
 Prorenin receptor, 725–726
 PROSCAR (finasteride), 1841
 PROSOM (estazolam), 466*t*
 Prostacyclin (PGI₂), 937
 catabolism of, 942
 effects on platelets, 949
 Prostacyclin (PGI₂) (Cont.):
 and gastric acid secretion, 950
 and gastrointestinal muscle, 950
 in inflammation, 960
 and intestinal secretions, 950
 pain and, 961
 Prostacyclin synthase, 939
 Prostaglandin analogs, 1314–1315
 for glaucoma, 1787
 Prostaglandin D, 939
 Prostaglandin D₂, 939
 catabolism of, 942
 in inflammation, 960
 Prostaglandin E, 939
 and gastric/intestinal secretions, 950
 and gastrointestinal muscle, 950
 and uterus, 950
 Prostaglandin E₁, history of, 937
 Prostaglandin E₂, 939
 for cervical ripening, 952
 in inflammation, 960
 pain and, 961
 Prostaglandin F
 and gastrointestinal muscle, 950
 and tracheal muscle, 950
 and uterus, 950
 Prostaglandin F_{1α}, history of, 937
 Prostaglandin F_{2α}, pain and, 961
 Prostaglandin H₂, 939
 metabolism, inhibition of, 942
 Prostaglandin(s) (PG), 926, 927*f*
 biosynthesis of, inhibition of, NSAIDs and, 963–965
 cardiovascular effects of, 946–947
 and cervical ripening, 1849–1850
 for claudication, 772
 endogenous, functions of, 946–948
 history of, 937
 in inflammation, 960–961
 and pain, 951
 PGE₁, therapeutic uses of, for impotence, 952
 as pruritogens, 1815
 pulmonary effects of, 947
 receptors, 944*t*
 renal effects of, 947–948, 950
 and vasopressin secretion, 704
 Prostaglandin (PG) receptors, 942–944, 944*t*
 Prostanoid receptor(s), 945*f*
 cell signaling pathways, 944–946
 expression, 944–946
 signaling pathways, 945*f*
 Prostanoids
 degradation of, 943*f*
 in inflammation, 960–961
 Prostate
 ABC transporters in, 106*t*
 alpha adrenergic receptors in, 203*t*
 Prostate cancer
 drugs for, 1668*t*–1670*t*
 hormone therapy in, 1763–1767
 Prostatic hyperplasia, benign, alpha-adrenergic receptor antagonists for, 308
 PROSTIN E2 (dinoprostone), 1837
 PROSTIN VR PEDIATRIC (alprostadil), 952
 Protamine sulfate, 858
 Protease inhibitors
 ABC transporters and, 105*t*, 106*t*
 atazanavir, 1652–1653
 darunavir, 1653–1654
 distribution of, 25
 efflux transporters and, 25
 fosamprenavir, 1650–1651
 for human immunodeficiency virus, 1644–1656
 indinavir, 1654
 lopinavir, 1651
 polymorphisms and response to, 159*t*
 for pulmonary disease, 1056
 ritonavir, 1649–1650
 and statins, interactions, 896
 tipranavir, 1655–1656
 Proteasome inhibitor, 1742–1743
 Protein(s), plasma, distribution and, 24
 Protein binding interaction, 77
 Protein C, 853
 deficiency of, 864
 Protein kinase(s). *See also* Protein tyrosine kinase inhibitors
 classification of, 1731
 Protein kinase C (PKC), inhibitors, 1012
 Protein S, deficiency of, 864
 Protein therapeutics
 examples of, 5

 physiological, 41–42
 cellular pathways activated by, 51–52
 functional families of, 52–55
 structural families of, 52–55
 potency and, 44–45
 purinergic, 391*t*
 quantification of agonism and, 46
 quantification of antagonism and, 46
 regulation of, 67–68
- Receptors (*Cont.*):
 response and, 45–46
 second messengers and, 55–58
 signal amplification and, 52
 subtypes of, 53–54
 transcription factors and, 65–66
 transmembrane, 53*t*
 transporter expression and, 97, 98*t*–99*t*
 voltage-gated channels and, 59
- Recombinant DNA technology, protein therapeutics and, 4, 5
- Recombinant human growth hormone, 1115–1117
- Rectal administration of drugs, 21–22
 opioids, 518
- Redistribution of drugs, 25
- Red-man syndrome, 914
- Re-entry
 anatomically defined, 820–822
 functionally defined (leading circle), 822–823, 823*f*
- Refills, in prescription writing, 1881–1882
- Regulatory region polymorphism, 155*t*
- Relapsing polychondritis, dapsone for, 1823
- Relcovaptan, 715*t*, 717
- RELENZA (zanamivir), 1596*t*
- REMICADE (infliximab), 1827
- Remifentanyl
 absorption, fate, and excretion of, 508
 pharmacokinetics of, 1883*t*
 structure of, 504*f*
 therapeutic uses of, 508
- Remikiren, 745
- Remoxipride, potencies at neurotransmitter receptors, 427*t*
- Renal anatomy and physiology, 671–677, 672*f*
 and organic acid and organic base secretion, 676
- Renal blood flow, angiotensin II and, 727*f*
- Renal cell carcinoma, 1744
 drugs for, 1668*t*–1670*t*
 metastatic, 1740
- Renal clearance, 30
- Renal epithelial transport, 675*f*
 ATP-mediated transport in, 674
 carrier-mediated (facilitated) diffusion in, 674
 channel-mediated diffusion in, 674
 secondary active transport in, 674
- Renal epithelial transport (*Cont.*):
 solvent drag in, 674
 symport and antiport in, 674
- Renal excretion, 26
- Renal failure
 ACE inhibitors in, 735
 chronic, diuretics for, 699
 fibric acid agents and, 903
- Renal osteodystrophy, 1289, 1290, 1293
- Renal transporters, 111–115
- RENESE (polythiazide), 688*t*
- Renin, 721–724
 pharmacological inhibition of, 724*f*
 release
 β -adrenergic receptor pathway, 722, 723*f*, 724
 intrarenal baroreceptor pathway, 722, 723*f*, 724
 long-loop negative feedback mechanism and, 723*f*, 724
 macula densa pathway, 722, 723*f*
 regulation of, 722, 723*f*
 short-loop negative feedback mechanism and, 723*f*, 724
- Renin-angiotensin-aldosterone axis, 794*f*, 797
 antagonists, 797
- Renin-angiotensin system, 721–730, 927*f*
 and arterial blood pressure maintenance, 730
 components of, 721–727, 722*f*
 effects of, 727–730
 functions of, 727–730
 history of, 721
 inhibitors, 730–736, 731*f* (*See also* Angiotensin-converting enzyme inhibitors (ACEI))
 nonpeptide angiotensin II receptor antagonists, 736–745
 local, 725–726
 extrinsic, 725–726
 intrinsic, 725–726
 response to pharmacological lowering of blood pressure, 746*t*, 747
 and vascular disease, 730
- Renin inhibitors, direct, 730, 731*f*
 absorption, 786
 as antihypertensive agents, 774*t*, 786
 effects on renin-angiotensin system, 746*t*
 excretion, 786
 for heart failure, 799
 hemodynamic effects of, with long-term administration, 774*t*

- Renin inhibitors, direct (*Cont.*):
 history of, 745
 mechanism of action of, 786
 metabolism, 786
 pharmacology of, 786
 precautions with, 786
 site of action of, 786
 therapeutic uses of, 786
 toxicity of, 786
 Renin receptor, 725–726
 Repaglinide, 110, 1258
 pharmacokinetics of, 1883*t*
 Repolarization, cardiac cell, sodium
 and calcium exchange in,
 802*f*
 Reporting, of adverse effects, 10
 REPREXAIN (hydrocortone +
 ibuprofen), 988
 Reproduction
 eicosanoids and, 948
 platelet-activating factor and, 954
 Reproductive tract, female
 cyclical gonadal steroids and, 1169
 infections, 1841, 1842*t*
 RESCRIPTOR (delavirdine), 1626*t*
 Research, preclinical, 6–7
 Reserpine
 absorption, fate, and excretion of,
 783
 as antihypertensive agent, 774*t*, 783
 cholinergic receptors and, 206*t*
 mechanism of action of, 783
 pharmacology of, 783
 precautions with, 783
 site of action of, 783
 SLC transporters and, 102*t*
 source of, 783
 structure of, 783
 therapeutic uses of, 783
 toxicity of, 783
 Resistance
 antimicrobial
 evolutionary basis of, 1377–1378
 mechanisms of, 1375–1377
 transporters and, 91, 103
 Respiratory paralysis, neuromuscular
 blocking agents and, 268
 Respiratory system
 acetylcholine and, 221
 amphetamines and, 298
 beta-adrenergic receptor antagonists
 and, 315, 316–317
 carbon dioxide and, 562
 epinephrine and, 285
 halothane and, 547
 ipratropium and, 230
 Respiratory system (*Cont.*):
 isoflurane and, 548
 methacholine and, 224
 muscarinic antagonists and, 228,
 231
 opioids and, 493–494
 oxygen inhalation and, 559
 tiotropium and, 230
 Respiratory tract, allergies of, H₁-
 receptor antagonists for,
 920–922
 Respiratory tract disease, kinins and,
 931
 Respiratory tract infections, drugs for,
 TMP-SMX, 1469
 Response
 exogenous factors in, 146*f*
 pharmacogenetics and, 145–146
 polymorphisms and, examples of,
 159*t*
 receptors and, 45–46
 RESTASIS (cyclosporine), 1790
 Restless leg syndrome (RLS), 358
 RESTORIL (temazepam), 466*t*
 Retapamulin, for impetigo, 1817
 Retina, 1774, 1776*f*, 1778
 systemic agents affecting, 1792
 Retinitis, parasitic, 1783
 Retinoic acid
 mechanism of action of, 1798
 structure of, 1796*f*
 9-*cis*-Retinoic acid, 1809
 13-*cis*-Retinoic acid, 1809
 all-*trans*-Retinoic acid, 1809

 Retinoic acid receptor (RAR), 97, 140*t*
 Retinoic acid receptors (RARs), 1809
 isoforms, 1809
 Retinoic acid-responsive elements
 (RAREs), 1809
 Retinoid dermatitis, 1812
 Retinoid receptor(s), 1809
 Retinoids
 for acne, 1809
 adverse effects and side effects of,
 1811–1812
 aromatic, 1809
 for cancer, 1722–1723
 contraindications to, 1811
 definition of, 1809
 dermatological uses of, 1809
 first-generation, 1809
 functions in body, 1809
 for photoaging, 1809
 for psoriasis, 1809
 second-generation, 1809
 Retinoids (*Cont.*):
 systemic, 1811–1812, 1811*t*
 and serum lipids, 1812
 teratogenicity of, 1812
 third-generation, 1809
 topical, 1810*t*
 Retinoid X receptor (RXR), 140*t*, 1809
 isoforms, 1809
 Retinoid X receptors, 1798
 Retinol, 1809
 isomers, 1795
 Retinoscopy, cycloplegic, autonomic
 agents for, 1785*t*
 Retrobulbar region, 1773
 RETROVIR (zidovudine), 1626*t*
 REVATIO (sildenafil), 758–759, 805,
 1792
 “Reversible” carbamate inhibitors,
 242
 REVLIMID (lenalidomide), 1742
 Rewarding properties, of opioids,
 493–494
 Reye’s syndrome, 975–976
 Rhabdomyolysis, statins and, 896
 Rhabdomyosarcoma, drugs for,
 1668*t*–1670*t*
 Rheologic modifiers, 771–772
 Rheumatic disorders, glucocorticoids
 for, 1232
 Rheumatic fever, penicillin for, 1487
 Rheumatoid arthritis, 960
 Rheumatoid arthritis (RA), biological
 agents for, 1825*t*
 RHEUMATREX (methotrexate), 1820
 Rhinorrhea, muscarinic antagonists
 and, 231
 Rh-null regulator, 103*t*
 Rho(D) immune globulin, 1024
 Ribavirin, 1596*t*, 1612–1614
 pharmacokinetics of, 1883*t*
 Riboflavin, 1086
 Rickets, 1289, 1293
 Rickettsial infections
 cephalosporins for, 1528
 conjunctivitis caused by, 1782
 Rifabutin, 1549–1554
 ocular effects of, 1793
 Rifampin, 1549–1554
 optic neuropathy caused by, 1792
 pharmacokinetics of, 1883*t*
 Rifamycins, 1549–1554
 Rifapentine, 1549–1554
 Riluzole, 625
 pharmacokinetics of, 1884*t*
 Rimantadine, 1596*t*, 1605–1607
 RIOFAN PLUS DOUBLE STRENGTH, 1316*t*

 pharmacokinetics of, 1887*t*
 structure of, 893*f*
 therapeutic uses of, 897
 in children, 898
- SINEQUAN (doxepin hydrochloride), 921*t*
- Single-nephron glomerular filtration rate (SNGFR), 671–673
- Single nucleotide polymorphisms (SNPs), 145, 147*f*, 148
- Sinoatrial node, in autonomic nervous system, 178*t*
- Sinoatrial (SA) node, acetylcholine and, 221
- Sinus bradycardia
 angina pectoris with, recommended treatment for, 769*t*
 drug-induced, 821*t*
- Sinus tachycardia
 angina pectoris with, recommended treatment for, 769*t*
 drug-induced, 821*t*
- Sirolimus, 1012–1013, 1743
 endovascular stents eluting, 772
 pharmacokinetics of, 1887*t*
 structure of, 1744
- Sitagliptin, 1264–1265
 pharmacokinetics of, 1887*t*
- Sitosterolemia, 104*t*
- Sjögren's syndrome, xerostomia and, 224
- Skeletal muscle
 acetylcholinesterase and, 188
 adrenocorticosteroids and, 1221
 epinephrine and, 286
 ethanol and, 636–637
 neuromuscular blocking agents and, 258–261
- Skeletal organization, 1285
- Skin
 bacterial infections, 1817
 diseases, non-pharmacological therapy, 1803
 infestations, agents used to treat, 1818–1819
 lithium and, effects on, 449
 necrosis, oral anticoagulant-induced, 864
 opioids and, 498
 premalignant lesions of, drugs for, 1668*t*–1670*t*
 structure and function of, 1803–1804, 1804*f*, 1805*f*
 in topical application of drugs, 23
 in transdermal administration, 21
 viral infections, 1818
- Skin cancer, nonmelanoma, photochemotherapy for, 1815
- Skin rash, angiotensin converting enzyme inhibitors and, 736
- SLC. *See* Solute carrier (SLC) transporters
- Sleep
 amphetamines and, 298
 barbiturates and, 472
 benzodiazepines and, 460–461
 muscarinic antagonists and, 230
- Sleep-wakefulness cycle, 5-HT and, 343
- Small molecules
 as angiogenesis inhibitors, 1739
 antitumor activity, mechanism of action of, 1731
- Smoking
 cessation, 272
 and dyslipidemia treatment, 890
 and risk for coronary heart disease, 887*t*

- Smooth muscle
 amphetamines and, 297
 eicosanoids and, 950
 epinephrine and, 284–285
 extravascular, histamine effects on, 917–918
 H₁-receptor antagonists and, 918
 meperidine and, 506
 platelet-activating factor and, 954
 SN-38, 134*f*, 139–140
 Snake venoms, 211
 SNAP-25. *See* Synaptosomal protein 25 (SNAP-25)
 SNAP regulators (SNARES), 187–188, 199
 SNAPs. *See* Soluble NSF attachment proteins (SNAPs)
 SNARES. *See* SNAP regulators (SNARES)
 SNPs. *See* Single nucleotide polymorphisms (SNPs)
 Sodium
 angiotensin II and, 730
 reabsorption in renal tubules, angiotensin II and, 729
 restriction, for heart failure, 790
 Sodium bicarbonate, as antidote, 86*t*
 Sodium channel(s), 59
 and cardiac electrophysiology, 815–816, 816–817, 816*f*, 817*f*
 in cardiomyocytes, 802*f*
 in neurotransmission, 182
 Sodium channel blockers
 antiarrhythmic use of, 826*f*, 827, 827*f*, 828
 antidote for, 86*t*
 cardiac electrophysiological actions of, 829*t*
 contraindications to, 833*t*
 Sodium ferric gluconate, 1085
 Sodium galactose transporter (vSGLT), 99
 Sodium iodide, parenteral, 1153*t*
 Sodium nitroprusside
 absorption, fate, and excretion of, 782
 as antihypertensive agent, 774*t*, 781–783
 mechanism of action of, 781–782
 pharmacological properties of, 753, 782
 site of action of, 781–782
 therapeutic uses of
 for heart failure, 795–796
 for hypertension, 782–783
 toxicity and precautions with, 782
 Sodium-potassium ATPase, 95
 inhibition by cardiac glycosides, 801
 Sodium pump. *See* Sodium-potassium ATPase
 Sodium salicylate
 COX isoform selectivity, 962*f*
 pharmacology of, 962*f*
 plasma pharmacokinetics of, 962*f*
 Sodium stibogluconate
 absorption, fate, and excretion of, 1436
 antiprotozoal effects of, 1436
 resistance to, 1436
 therapeutic uses of, 1436
 toxicity and side effects of, 1436
 Sodium-taurocholate cotransporting polypeptide (NTCP), 93
 Soft tissue infections, quinolones for, 1473
 SOLAGE (mequinol), 1830
 SOLAREZE (diclofenac), 986
 Solatene, 1813
 Solifenacin
 dosing of, 232*t*
 metabolism of, 232
 for overactive bladder, 231
 pharmacokinetics of, 1888*t*
 Solitary tract nucleus (STN), 171
 Soluble epoxide hydrolase (sEH), 130
 Soluble guanylate cyclase, 64–65
 Soluble NSF attachment proteins (SNAPs), 199
 SOLU-MEDROL (methylprednisolone sodium succinate), 1809
 Solute carrier (SLC) transporters, 89, 96
 Solute carrier (SLC) transporter superfamily, 99–108, 102*t*–103*t*
 Solutes, transmembrane transport, mechanisms, 674*f*
 Solution(s), of topical drugs, 1807*t*
 Solvent drag, 671, 674
 Soman, 239, 243
 Somatostatin, 172, 182
 for diarrhea, 1338–1339
 Somatostatin analogs, 1112–1113
 Somatotrophic hormones, 1106–1117, 1106*t*
 Sorafenib, 1739
 absorption, 1740
 adverse effects and side effects of, 1740
 chemistry, 1740
 distribution of, 1740
 elimination, 1740
 pharmacokinetics of, 1888*t*
 Sorafenib (*Cont.*):
 structure of, 1740
 therapeutic uses of, 1740
 SORBITRATE (isosorbide dinitrate), 754*t*
 SORIATANE (acitretin), 1812
 SORIATANE CK (acitretin), 1812
 Sotalol
 antiarrhythmic use of, 831–832, 836*t*, 845
 arrhythmias caused by, 821*t*
 contraindications to, 833*t*
 dosage of, 836*t*
 electrophysiological actions of, 829*t*
 mechanism of action of, 830
 pharmacokinetics of, 836*t*, 1888*t*
 structure of, 845
 Sources of drugs, 4–5
 Sparteine, 156
 polymorphisms and response to, 159*t*
 Specificity, of drug effects, 42–43
 SPECTAZOLE (econazole), 1818
 Spectinomycin, 1538
 Spermicide, one-year failure rate, 1834*t*
 SPF. *See* Sun protection factor (SPF)
 Spinal analgesics, 516–518
 Spinal anesthesia, 577–578
 Spinal cord, 364
 alpha adrenergic receptors in, 203*t*
 beta adrenergic receptors in, 204*t*
 injury, corticosteroids for, 1235
 Spinal visceral afferent system, 171
 Spiradoline, actions and selectivities, 485*t*
 Spironolactone, 692–695
 absorption and elimination of, 693*t*, 694
 adverse effects and side effects of, 694–695
 as antihypertensive agent, 774*t*, 778
 contraindications to, 694–695
 drug interactions with, 694–695
 effects on renal hemodynamics, 694
 effects on urinary excretion, 693–694
 mechanism of action of, 1841
 pharmacokinetics of, 1889*t*
 pharmacology of, 693*t*
 structure of, 693*t*
 therapeutic uses of, 695, 1841
 for heart failure, 791
 toxicity of, 694–695
 Spleen, alpha adrenergic receptors in, 203*t*
 Spleen capsule, in autonomic nervous system, 179*t*

- SPORANOX (itraconazole), 1818
 SPRYCEL (dasatinib), 1732
 Squamous cell carcinoma (SCC)
 bleomycin for, 1823
 prevention of, sunscreens and, 1828
 SR 16234, 1756, 1759
 SR 49059, 715*t*, 717
 SR 121463A, 715*t*
 SREBP. *See* Sterol regulatory element–binding protein (SREBP)

 structure and function of, 1803, 1804*f*
 thickness, 1803, 1804*f*
 Streptococcal infections, penicillin for, 1486
Streptococcus pyogenes, pyoderma caused by, 1817
 Streptogramins, 1535–1537
 Streptokinase, 866
 pharmacokinetics of, 1889*t*
 Streptomycin, 1517
 Streptozocin, 1668*t*–1670*t*
 Stress-related ulcers, 1321
 Stress response, ACTH secretion and, 1214
 STROMEKTOL (ivermectin), 1819
 Stromelysin-1 polymorphism, 161*t*
Strongyloides stercoralis, 1445–1446, 1456
 Structure-activity relationships, drug design and, 43–44
 Study design, pharmacogenetic, 151–165
 Subcorneal pustular dermatosis, dapsone for, 1823
 Subcutaneous administration, 20*t*, 22
 Sublingual administration, 21
 Submucosal plexus, 174, 175
 Subscription, in prescription, 1879
 Substance abuse. *See* Drug abuse and addiction
 Substance P, 172, 182
 and vasopressin secretion, 704
 Substance P receptor antagonists, as antinausea agent, 1344
 Substituted urea(s), for neoplastic disease, 1668*t*–1670*t*
 Substrates, transporters and, 93, 94*f*
 Succimer, 1874
 as antidote, 86*t*
 Succinimides, 596
 Succinylcholine
 action of, 260
 characteristics of, 264*t*
 dosing of, 265*t*
 histamine and, 914
 paralysis with, 261
 structure of, 259*f*

- Sucralfate
adverse effects of, 1315
chemistry of, 1315
mechanism of action of, 1315
pharmacological properties of, 1315
therapeutic uses of, 1315
- Sufentanil
actions and selectivities of, 485*t*
dosage of, 500*t*
structure of, 504*f*
- Sulbactam/ampicillin, hypoglycemia and, 1248*t*
- Sulconazole, 1588, 1817
- Sulfacetamide
for acne, 1817
pharmacological properties of, 1466
- SULFACET-R (sulfacetamide/sulfur), 1817
- Sulfadoxine, pharmacological properties of, 1467
- Sulfamethoxazole
pharmacokinetics of, 1889*t*
pharmacological properties of, 1466
- Sulfanilamide, Food and Drug Act and, 7
- Sulfapyridine, 1354–1356
- Sulfasalazine, 994*t*
pharmacological properties of, 1466
structure of, 977*f*
- Sulfate conjugates, 102*t*
- Sulfation, 128*t*, 133–135
- Sulfinpyrazone, hypoglycemia and, 1248*t*
- Sulfisoxazole, pharmacological properties of, 1465–1466
- Sulfonamides, 1410
absorption, fate, and excretion of, 1465
agranulocytosis caused by, 1467
antibacterial spectrum of, 1463–1464
aplastic anemia caused by, 1468
drug interactions with, 1468
hematopoietic effects of, 1467
hypersensitivity reactions to, 1468
hypoglycemia and, 1248*t*
mechanism of action of, 1464
microbe effects of, 1463–1465
pharmacological properties of, 1465–1467
polymorphisms and response to, 159*t*
prophylactic uses of, 1467
resistance to, 1465
side effects of, 138*t*
synergists of, 1464–1465
- Sulfonamides (*Cont.*):
therapeutic uses of, 1467
untoward reactions to, 1467–1468
urinary tract effects of, 1467
- Sulfonylureas
absorption, distribution, and elimination, 1256–1257
adverse reactions to, 1257
antidote, 86*t*
chemistry of, 1256
dosage forms available, 1257
drug interactions with, 1257
manifestation of overdose symptoms, 75*t*
mechanism of action of, 1256
therapeutic uses of, 1258
- Sulfotransferases (STs), 125
- Sulfotransferases (SULT), 125*t*, 132, 133–135
- Sulfur, keratolytic effect of, 1829
- Sulfur hexafluoride, as vitreous substitute in surgery, 1790
- Sulfur in petrolatum, 1819
- Sulindac, 985
absorption, 985
adverse effects and side effects of, 985
in cancer prevention, 972–973
compared to aspirin, 967*t*
COX isoform selectivity, 962*f*
distribution of, 985
dosage and administration of, 967*t*
elimination, 985
mechanism of action of, 985
pharmacokinetics of, 967*t*, 985
pharmacology of, 962*f*
plasma pharmacokinetics of, 962*f*
structure of, 985
therapeutic uses of, 967*t*, 985
- Sulpiride, potencies at neurotransmitter receptors, 427*t*
- Sulprostone, for pregnancy termination, 1837
- SULT. *See* Sulfotransferases (SULT)
- Sumatriptan
arrhythmias caused by, 832
pharmacokinetics of, 1889*t*
- SUMYCIN (tetracycline), 1817
- Sunitinib, 1739
dosing, 1740
mechanism of action of, 1740
pharmacokinetics of, 1740, 1890*t*
structure of, 1740
therapeutic uses of, 1740
toxicity of, 1740
- Sun protection factor (SPF), 1827–1828
- Sunscreens, 1827–1828
UVA, 1827–1828
UVB, 1827–1828
- Superior mesenteric ganglion, 173*f*
- Superscription, 1879
- Suppositories, 1335–1336
- Supraventricular tachycardia, angina pectoris with, recommended treatment for, 769*t*
- SUPREFACT (buserelin), 1119*t*, 1765
- Suramin
absorption, fate, and excretion of, 1437
antiparasitic effects of, 1437
contraindications to, 1438
precautions with, 1438
therapeutic uses of, 1437
toxicity and side effects of, 1437–1438
- Surrogate end points, 9
- Susceptibility testing, antimicrobial agents and, 1369–1371
- Sustained-release formulations, 21
manifestation of overdose symptoms, 75*t*
- SUSTIVA (efavirenz), 1626*t*
- Sweat glands, muscarinic antagonists and, 229–230
- Sweet's syndrome, dapsone for, 1823
- “Swiss cheese” model of medication error, 81*t*
- SXR. *See* Steroid X receptor (SXR)
- SYMADINE (amantadine), 1596*t*
- SYMMETREL (amantadine), 1596*t*
- Sympathetic ganglia, 176
- Sympathetic system, 171, 172–174
- Sympatholytic agents
as antihypertensive agents, 774*t*, 778–780
hemodynamic effects of, with long-term administration, 774*t*
- Sympathomimetic amines
for allergies, 302–303
for arrhythmias, 302
for asthma, 302
for attention-deficit/hyperactivity disorder, 303–304
chemistry and structure-activity relationship, 278–281
false-transmitter concept, 282
for heart failure, 302
for hypotension, 301–302
indirectly acting, 282
for narcolepsy, 303

- Sympathomimetic amines (*Cont.*):
 for shock, 301
 structure-activity relationship of, 278–281
 substitution on α -carbon, 281
 substitution on aromatic nucleus, 281
 substitution on β -carbon, 281
 therapeutic uses of, 300–304
 for weight loss, 303
- Sympathomimetics, classification of, 274–277
- Sympathomimetic toxidrome, 83*t*
- Symport, 674

Introduction to Toxicology

Toxicology

Formerly

The Science of *Poisons*

Now

**The science that deals with the
adverse effects of chemicals on
living organisms and assesses
the probability of their
occurrence**

Outline

- History of Toxicology
- Dose Response
- Types of Toxicants
- Case Studies of alcohol and lead
- The Future

Historical Perspective

“...the appearance of disease in human populations is influenced by the quality of air, water, and food; the topography of the land; and general living habits.”

**The ancient-Greek physician Hippocrates
in his treatise Air, Water and Places**

400 BC

<http://classics.mit.edu/Hippocrates/airwatpl.mb.txt>

All substances are poisons;
there is none that is not a
poison.

The right dose
differentiates a poison and a
remedy.

Paracelsus (1493-1541)
The Father of Modern Toxicology

History

Spanish physician Orfila (1815)
established
toxicology as
a distinct scientific discipline.

Toxicology Today

Mechanistic toxicology: The study of how a chemical causes toxic effects by investigating its absorption, distribution, and excretion.

Descriptive toxicology: The toxic properties of chemical agents are systematically studied for various endpoints using a variety of different organisms.

Clinical toxicology: They study of toxic effects of various drugs in the body, and are also concerned with the treatment and prevention of drug toxicity in the population.

Toxicology Today

Forensic toxicology: A branch of medicine that focuses on medical evidence of poisoning, and tries to establish the extent to which poisons were involved in human deaths.

Environmental toxicology: The study of the effects of pollutants on organisms, populations, ecosystems, and the biosphere.

Regulatory toxicology: The use scientific data to decide how to protect humans and animals from excessive risk. Public or Private Sector.

Dose

The amount of chemical entering the body This is usually given as **mg of chemical/kg of body weight = mg/kg** The dose is dependent upon

- * The concentration**
- * The properties of the toxicant**
- * The timing and frequency of exposure**
- * The length of exposure**
- * The exposure pathway**

What is a Response?

**The degree of responses depend upon
the dose and the organism**

- **Change from normal state**
 - **could be on the molecular, cellular, organ, or organism level--the symptoms**
- **Local vs. Systemic**
- **Reversible vs. Irreversible**
- **Immediate vs. Delayed**
- **Monotonic – response increases with dose (cyanide and many traditional toxicants)**
- **Nonmonotonic – response does not increase with dose (hormones, endocrine disruptors, micronutrients and vitamins)**

CHEMICALS: Major Types of Toxicity

- **Toxins – biological compounds (Ricin, botulism)**
- **Carcinogens - may induce cancer or increase its incidence and can affect any cells or tissues (benzene, vinyl chloride, benzo(a)pyrene)**
- **Mutagen - may induce hereditary genetic defects or increase their incidence and effect on the germ cells (gonads). (radiation, nitrosoamines)**
- **Teratogens - may induce non-hereditary congenital malformations or increase their incidence and effect on the growing fetus (*rubella*, thalidomide, PCBs, Dioxins)**
- **Endocrine disruptor – hormone mimic (PBDE, BPA)**

CHEMICALS: Major Types of Toxicity

- **Chronic toxicity: It involves Sub-lethal concentration and long-term exposure**
- **Chronic toxicity test is used to derive Effective Dose (ED_{50}): Is the dose by which half of the population has been affected**
- **Effect could be anything but death**
- **ED_{50} is obtained by plotting, for a given dose the proportion of the population that responded to that dose and all lower doses**

CHEMICALS: Major Types of Toxicity

- **Acute toxicity: It involves lethal concentrations and short-term exposures**
- **The end point is usually death**
- **An LD₅₀ is a dose of a toxic chemical that kills half of the population.**
- **LD₅₀ is obtained by plotting, for a given dose the proportion of the population that responded to that dose and all lower doses**

Monotonic Dose Response

CHEMICALS: Major Types of Toxicity

- **No Observable Adverse Effect Level (NOAEL)** – the threshold where no effects are observed.
- **Lowest Observable Adverse Effect Level (LOAEL)** – the concentration level where effects are observed.

Potency – concentration to produce an effect.

CHEMICALS: Major Types of Toxicity

Cancer causing chemicals are assessed by risk

- **One mutation has an inherent risk so one molecule of a toxicant may pose a theoretical risk.**
- **Organisms have repair functions for protection**
- **1:1,000,000 risk is considered acceptable. (note: we can only measure 1:100 in the laboratory and must extrapolate the low risk level).**
- **Toxicity cannot be estimated by high dose experiments**

**Hormesis – U shaped dose response curve
(nonmonotonic)**

- **Characterized by a low dose stimulation or beneficial effect and a high dose inhibitory or toxic effect.**
- **Essential nutrients, vitamins, ionizing radiation, aspirin, alcohol**

Dose Response Curves

Dose-Effect Curves

Endocrine disruptors:

- **Synthetic or naturally occurring chemicals that affect the Endocrine or hormonal system of animals**
- **May either:**
 - **Mimic hormones**
 - **Block hormone activities**
 - **Directly stimulate or inhibit the endocrine system**

Hormones and Endocrine Disruptors

- **Bind to receptor molecules**
- **Nonmonotonic dose response curves**
- **Stimulate at low doses**
- **No increasing effect at high doses due to receptor saturation**
- **Very complex reactions and cross reactivity**
- **Very low doses are significant**
- **Effect cannot be estimated by high dose toxicity testing**

Endocrine Disruptors

(a) Normal hormone binding

(b) Hormone mimicry

Some chemicals, once inside the bloodstream, can “mimic” hormones.

If molecules of the chemical bind to the sites intended for hormone binding, they cause an inappropriate response.

Thus these chemicals *disrupt* the *endocrine* (hormone) system.

Tamoxifen and Cancer

Estrogen molecule binds to estrogen receptor

Estrogen receptor acquires changed shape

Estrogen receptor binds to coactivators

Tamoxifen molecule binds to estrogen receptor

Tamoxifen receptor does **not** acquire changed shape

Tamoxifen receptor cannot bind to coactivators

Perceptions About Chemicals

- What drives our perceptions? Are chemicals bad?

HUMAN RISK PERCEPTION... is affected by the degree of pleasure / displeasure associated with the particular risk

Agent	LD-50 (mg/kg)
Ethyl alcohol	10,000
Salt (sodium chloride)	4,000
Iron (Ferrous sulfate)	1,500
Morphine	900
Mothballs (paradichlorobenzene)	500
Aspirin	250
DDT	250
Cyanide	10
Nicotine	1
Tetrodotoxin (from fish)	0.01
Botulinum Toxin	0.0000
	1

What type of toxic chemical is alcohol ?

- **Group 1 known Human Carcinogen**
- **Exhibits hormesis – small amounts are beneficial (cardiovascular system)**
- **Teratogen - fetal alcohol syndrome**

“Of all the substances of abuse (including cocaine, heroin, and marijuana), alcohol produces by far the most serious neurobehavioral effects in the fetus.”

—Institute of Medicine Report to Congress, 1996.

Fetal Alcohol Syndrome Facts

- **Alcohol diffuses through placenta**
- **Concentration in fetal blood is the same as in the mother's blood within a few minutes**
- **The fetus is able to metabolize alcohol 10% as fast as the mother**
- **1 in 200 individuals are affected by prenatal alcohol exposure.**

Sequence of Human Development

Embryonic Development

Developmental Progression & Susceptibility to Teratogens & Fetal Loss

(Modified from Keith Moore, *The Developing Human: Clinically Oriented Embryology*, 3rd Ed., W.B. Saunders Co.: Philadelphia, PA, 1983.)

Black- most sensitive

What is lead

- Lead is a soft gray metal element that occurs naturally in the earth.
- For many years, lead was added
 - to paint,
 - gasoline,
 - Pipes and solder
 - batteries
- Banned in 1973 in paint
- Banned in 1976 in gasoline
- Banned in solder in 1993

What are the Sources of Lead

- Homes that have cracked and peeling old lead paint on their walls.
- Home renovations that disturb old lead paint can spread invisible lead dust.
- Lead from old lead paint may contaminate household dust and nearby soil.

How are people exposed to lead?

- Ingestion of foods, water, alcohol may be significant for certain populations.
- Ingestion of dusts is primary way general population, especially children, are exposed to lead.
- Inhalation of lead dust contributes to a build up in the body.

Childhood Risk Factors for Elevated BLLs

(>10µg/dl)

Pre-1946 Housing

Non-Hispanic Black	21.9%
Mexican American	13.0%
White	5.6%

Low Income	16.4%
High Income	0.9%

NHANES III, and CDC Recommendations for BL Screening
of Young Children (Dec. 2000)

SOURCES OF LEAD-

House Dust

Uncontaminated- New inner-city home

Floor Surface- 2-24 $\mu\text{g}/\text{sq ft}$

Contaminated- Old inner-city home

Floor Surface- 33-486
 $\mu\text{g}/\text{sq ft}$

How Does Lead Enter the Body?

Ingestion

Adults absorb about 6% of ingested lead. Fasting adults absorb **more**.

Children absorb **much more** lead (30-50% if well fed, and more, if fasting or malnourished).

It takes **>10 years** to turn over one half
th

e body's stored lead. Bone source slowly leaches into the blood.

Lead Exposure *in utero*

- Lead crosses the placenta in plasma.
- Pregnancy (and lactation) causes lead release from bone stores into plasma
- Plasma lead is about 10% of circulating blood lead.
- Epidemiologic effects on CNS have been documented.
- Peak transfer is at 12-14 weeks gestation

Cognitive Performance

Deficits in Lead-

Deficits in Exposed Children

Psychomotor performance

Auditory and language
processing

Sustained attention &
concentration

Measured outcomes:

Less likely to graduate High

School More likely to be convicted
of felonies

What happens when lead enters the body

- Lead is stored for long periods in mineralizing tissue such as teeth and bones.
- Lead is can be released again into the bloodstream from these sources during times of bodily stress, such as
 - ~ pregnancy
 - ~ breastfeeding
 - ~ calcium deficiency
 - ~ osteoporosis (thinning of the bones)

Lead Exposure

- Most lead exposure in the U.S. today occurs in older homes with deteriorated leaded paint.
- Children are at greatest risk of lead poisoning from their homes.
- Most children are exposed to lead in dust (not by eating paint chips).

Lead in home environments (continued)

Lead in home dust

- The more lead in the dust in a home, the higher the levels of lead in children.
- There is no safe threshold for lead

What parts of the body does lead affect?

- The brain is very sensitive to lead.
- Exposure to high levels of lead can permanently affect the brain, bones, kidneys, and the heart.

What levels cause health effects

- Lead can cause harm even at very low levels, especially in young children.
- There is no safe threshold for lead.
- At very high levels, lead can brain damage, coma
- Adults experience similar effects, but generally at higher levels of exposure.

What are the effects of lead exposure on young children?

- Lowered IQ
- Learning disabilities
- Attention deficit and hyperactivity
- Other behavioral issues
- Impaired hearing
- Anemia
- Decreased growth

How to test for lead exposure

- Children should have their blood tested at ages one and two.
- Older children at risk of lead poisoning should also be tested.
- Adults who may be exposed to lead at work should also be tested.

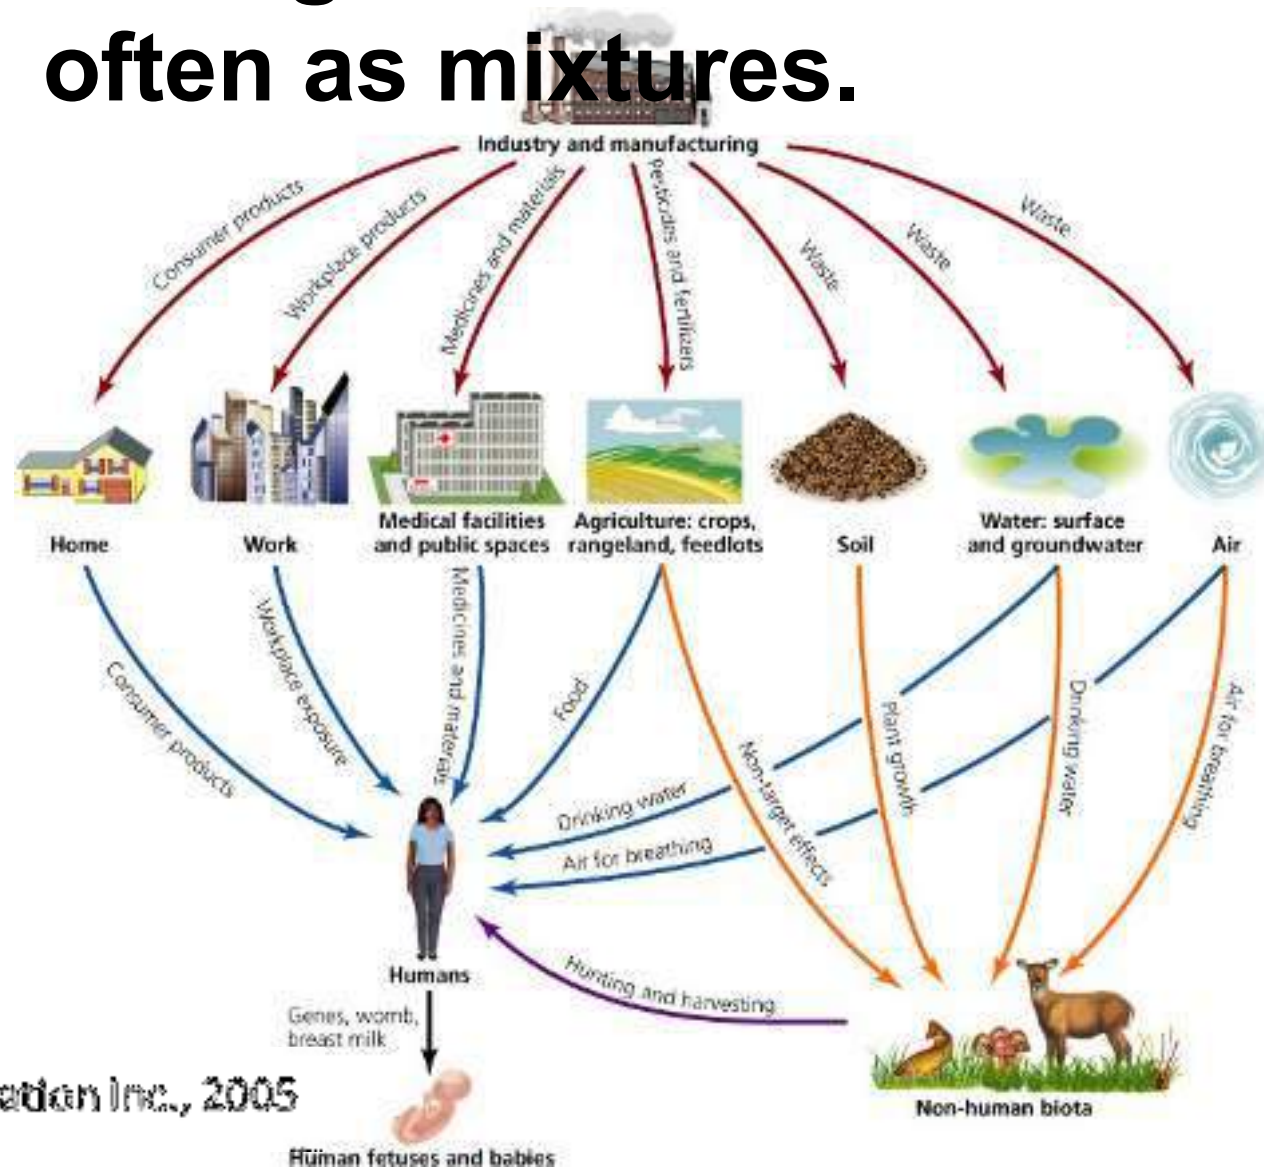

How to prevent lead exposure

- If your home was built before 1978, you should have it tested for lead.
- Make sure all paint is in good condition.
- Wet-clean all surfaces, especially window sills, at least every week.
- Wash children's hands frequently.
- Cover bare soil in the yard.
- Learn about lead-safe work practices when doing work on your home that disturbs paint.

Toxicants take many routes through the environment often as mixtures.

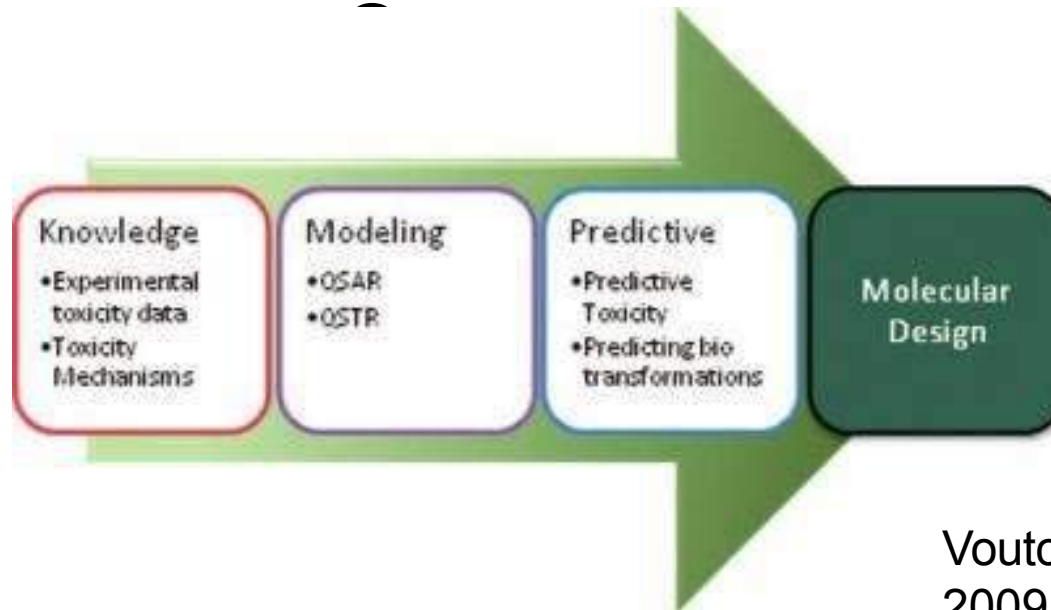

What is the role of Toxicology in Green Chemistry

- Linking molecular structure to hazard
- Focus less on minimizing risk through reducing exposure
- Focus more on minimizing hazard by designing safer chemicals
- $\text{Risk} = \text{Hazard} \times \text{Dose (Exposure)}$
- The hazardous nature of a substance can be controlled through structure manipulation

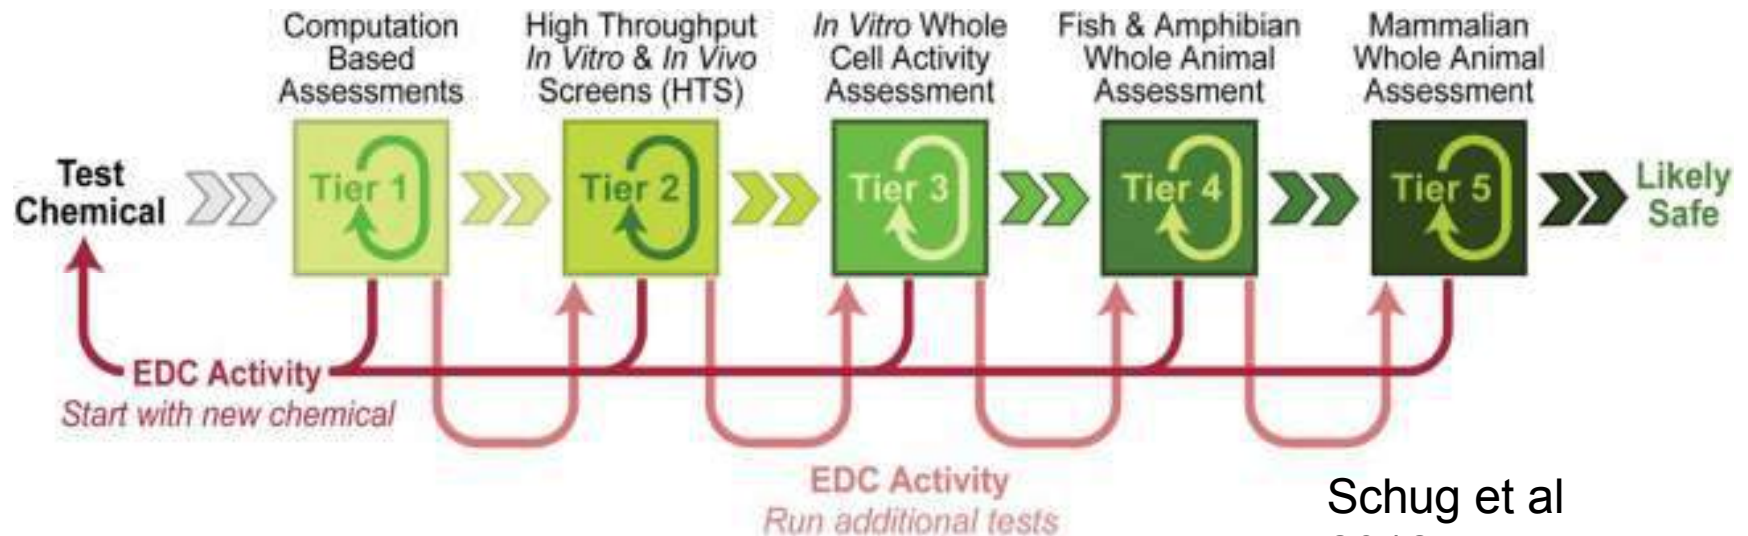

*NRC. 1983. Risk Assessment in the Federal Government: Managing the Process. National Research Council. National Academy Press, Washington, DC. ISBN: 0-309-03349-7.

Estrogen vs Hormonally Active Agents

mindfully.or
q

Estradiol

BPA

MBP

Summar

- Toxicology is a complex science based on the principle of dose and response.
- Environmental exposures further adds to this complexity.
- Focus more on minimizing hazard by designing safer chemicals
- Green chemistry can provide solutions!

Summar

Toxicology is ^ya fascinating science that makes biology and chemistry interesting and relevant.

Understanding HOW (i.e. mechanism)

something produces a toxic effect can lead to new ways of preventing or treating chemically-related diseases. Animal use in research is essential for medical progress.

Many diseases are the result of an interaction between our genetics (individual variability) and chemicals in our environment.

Toxicology provides an interesting and exciting way to apply science to important problems of social, environmental, and public health significance.

Your Role

Risk is a part of everyday life, and one's decisions as to the 'acceptability' of a particular risk is influenced by knowledge.

We can try to increase the public's knowledge about the risks and benefits of all things chemical.

You play a critical role in this effort, and we can't do it without YOU.

BP602T. PHARMACOLOGY-III (THEORY)

UNIT-I

**Prepared by
Nishant Singh Katiyar
Asst. Prof.
Rama University
Kanpur**

UNIT-I

10hours

1. Pharmacology of drugs acting on Respiratory system

- a. Anti -asthmatic drugs
- b. Drugs used in the management of COPD
- c. Expectorants and antitussives
- d. Nasal decongestants
- e. Respiratory stimulants

2. Pharmacology of drugs acting on the Gastrointestinal Tract

- a. Antiulcer agents.
- b. Drugs for constipation and diarrhoea.
- c. Appetite stimulants and suppressants.
- d. Digestants and carminatives.
- e. Emetics and anti-emetics.

DRUGS ACTING ON RESPIRATORY SYSTEM

DRUGS USED IN COUGH:

Introduction:

Cough is a protective reflex which helps in expulsion of respiratory secretion or foreign particles which are irritant to the respiratory tract. Irritation to any part of respiratory tract starting from pharynx to lungs carried impulses by afferent fibres in vagus and sympathetic nerve to the cough centre in the medulla oblongata. Cough may be **dry** (without sputum or unproductive) or **productive** (with sputum production). There are certain factors which are responsible for production of cough e.g.

- i) *Environmental factors*: Certain irritant pollutants, dust, smoking, automobile smoke.
- ii) Upper respiratory tract infection.
- iii) Acute lung infections, asthma and certain pleural diseases e.g. pleural effusion.
- iv) Chronic pulmonary ailments e.g. tuberculosis, chronic bronchitis & lung cancer etc.
- v) Drug induced cough (e.g. with the use of ACE inhibitors).

The drugs and their combination used in cough are discussed below.

1. *Pharyngeal demulcents*: Lozenges, cough drops, linctuses containing syrup, glycerine, liquorice.

2. *Expectorants (Mucokinetics)*:

(a) ***Bronchial secretion enhancers***: Sodium or Potassium citrate, Potassium iodide, Guaiphenesin (Glyceryl guaiacolate), balsum of Tolu, Vasaka, Ammonium chloride.

(b) ***Mucolytics***: Bromhexine, Ambroxol, Acetyl cysteine, Carbocisteine

3. *Antitussives (Cough centre suppressants)*

(a) **Opioids:** Codeine, Ethylmorphine, Pholcodeine.

(b) **Nonopioids:** Noscapine, Dextromethorphan, Chlophedianol.

(c) **Antihistamines:** Chlorpheniramine, Diphenhydramine, Promethazine.

(d) **Peripherally acting:** Prenoxdiazine.

4. Adjuvant antitussives:

Bronchodilators: Salbutamol, Terbutalin.

Pharyngeal Demulcents:

These are the agents which are generally administered in the form of lozenges, cough drops and cough linctus. They produce the soothing action on throat directly and by increasing the flow of saliva and provide symptomatic relief from dry cough.

Expectorant:

Expectorants are the drugs which increase the production of bronchial secretion and reduce its viscosity to facilitate its removal by coughing. Expectorants can stimulate the expulsion of respiratory secretion either directly or reflexly. Certain volatile oils of plant origin such as oil of lemon, anise, eucalyptus by steam inhalation route increase the respiratory secretion by its direct action. Another compound, syrup tolu (Tolu balsum) directly increase bronchial secretion.

The second type is reflex expectorant, which acts by stimulating the gastric reflexes which help to increase the respiratory secretions. Certain salts which are used as emetics, when used in sub emetic dose, increase the bronchial secretion and expel it out, they are known as **saline expectorants**.

Ammonium salts (as chloride and carbonate) are gastric irritant in nature and reflexly increase bronchial secretion.

Potassium salts (as iodide) act by both direct action and reflexly to increase the respiratory secretions and decrease its viscosity thus they are easy to expel out. Potassium iodide is generally used for cough associated with chronic bronchitis and asthma but it interferes with thyroid function tests, so it is dangerous in patients sensitive to iodine and chronic use can induce hypothyroidism and goitre.

Sodium and **potassium citrate** and **acetate** act by increasing bronchial secretion by their salt actions. Certain alkaloids such as **vasicine** obtained from plant *Adhatoda vasica* act as potent expectorant and mucolytic agent. **Bromhexine**, a derivative of vasicine depolymerises mucopolysaccharides directly and by liberating lysosomal enzymes. Another compound **acetylcysteine** opens disulfide bonds in mucoproteins present in sputum and decrease its viscosity. **Carbocisteine** acts in same manner.

Antitussives:

They are central cough suppressants and act centrally to raise the threshold of cough centre and inhibit the cough reflex by suppressing the coordinating cough centre in the medulla oblongata. They are mainly used in dry (unproductive) cough and are ineffective in cough due to pleural disease.

Codeine, which is an opium alkaloid is most commonly used as antitussive and is more selective for cough centre. Like morphine, it depresses cough centre but is less constipating and abuse liability is low. It is relatively safe drug used in cough along with analgesic property and it's only important adverse effect is constipation.

Pholcodeine is similar to codeine in efficacy and is longer acting. It has no analgesic or addicting property.

Noscapine is another opium alkaloid of benzyloquinoline group. It is used as antitussive with no analgesic and drug abuse or drug dependence property. It is contraindicated in asthmatic patients as it releases histamine which can cause bronchoconstriction.

Dextromethorphan is a synthetic compound and is used as antitussive and is as effective as codeine without any addiction liability.

Pipazethate is another synthetic compound of phenothiazine category used as antitussive with little analgesic and sedative properties.

Antihistaminics:

Many H1 antihistaminics have been added to antitussive/expectorant formulations. They do not act on cough centre but provide relief due to their sedative and anticholinergic action.

Bronchodilators:

Bronchodilators are helpful in individuals with cough and bronchoconstriction due to bronchial hyper-reactivity. They help by improving the effectiveness of cough in clearing secretions.

ANTIASTHMATIC DRUGS

Introduction:

Asthma is a disease characterized by an increased responsiveness of the trachea and bronchi to a variety of stimuli and manifests as narrowing of the airways that change in severity either spontaneously or as a result of therapy. The impairment of air flow in asthma is caused by three abnormalities:

- a) Constriction of bronchial smooth muscle (bronchoconstriction).
- b) Swelling of bronchiolar mucosa (bronchial edema).
- c) Excessive bronchial secretions.

Drugs used in management of bronchial asthma are discussed according to their main groups.

CLASSIFICATION:

I. Bronchodilators

A. β 2 Sympathomimetics: Salbutamol, Terbutaline, Bambuterol, Salmeterol, Formoterol, Ephedrine.

B. Methylxanthines: Theophylline (anhydrous), Aminophylline, Choline theophyllinate, Hydroxyethyl theophylline, Theophylline ethanolate of piperazine, Doxophylline.

C. Anticholinergics: Ipratropium bromide, Tiotropium bromide.

II. Leukotriene antagonists : Montelukast, Zafirlukast.

III. Mast cell stabilizers: Sodium cromoglycate, Ketotifen.

IV. Corticosteroids:

A. Systemic: Hydrocortisone, Prednisolone and others.

B. Inhalational: Beclomethasone dipropionate, Budesonide, Fluticasone propionate, Flunisolide, Ciclesonide.

V. Anti-IgE antibody: Omalizumab

Sympathomimetics:

β_2 -agonists are invariably used in the symptomatic treatment of asthma. Epinephrine and ephedrine are structurally related to the catecholamine norepinephrine, a neurotransmitter of the adrenergic nervous system. β_2 -agonists are the drug of choice to relieve acute exacerbation of asthma and prevent bronchoconstriction following exercise or other stimuli. After inhalation the β_2 -agonists have rapid onset of action (within minutes), but are active only for 4 to 6 hours. The detailed pharmacology is discussed in chapter 'Adrenergic Agents'.

Salbutamol is a highly selective β_2 -adrenergic stimulant having a prominent bronchodilator action. It is given by oral as well as inhalation route by nebulizer. Palpitation, restlessness, nervousness are the common side effects with salbutamol.

Terbutaline is similar to salbutamol and is administered by oral, parenteral as well as inhalational route.

Salmeterol is a newer long acting selective α_2 adrenergic agonist with slow onset of action, used for maintenance therapy in asthma, nocturnal asthma and asthma induced by exercise.

Methylxanthines (Theophylline and its Derivatives)

Among the methylxanthines, aminophylline is most commonly used drug in the treatment of bronchial asthma. It is a stable mixture of theophylline and ethylenediamine. These drugs inhibit the enzyme phosphodiesterase, this inhibition results in higher concentration of intracellular cyclic AMP. Increased cAMP leads to bronchodilatation, cardiac stimulation and vasodilatation.

Other important methylxanthines are caffeine and theobromine. Caffeine and theophylline are pharmacologically CNS stimulants and produce alertness and cortical arousal, but in higher doses causes restlessness, nervousness and insomnia. Methylxanthines stimulate the heart and increase the force of myocardial contraction. They relax smooth muscles especially bronchi in asthmatic patients.

Anticholinergics:

Anticholinergics, like atropine and its derivative ipratropium bromide block cholinergic pathways that cause airway constriction. They may provide added bronchodilator effect in patients who are receiving beta2-adrenergic agents for asthma.

The detailed pharmacology is discussed in chapter 'Cholinergic blocking agents.'

Mast Cell Stabilizers:

The important members in this group are sodium cromoglycate and ketotifen. They are highly effective in preventing asthma attacks. They inhibit degranulation of mast cells. These agents do not produce bronchodilatation and also do not antagonize the constrictor effect of histamine etc. Therefore they are not beneficial in acute attacks of asthma and are used for prophylaxis only.

Sodium cromoglycate is not absorbed orally and is administered by aerosol. The most important therapeutic uses of mast cell stabilizers is the prophylaxis of bronchial asthma, treatment of nasal congestion and chronic allergic conjunctivitis.

Corticosteroids:

Like mast cell stabilizer, corticosteroids do not relax airway smooth muscle directly but reduce bronchial reactivity, increase airway caliber, suppress inflammatory response to antigen antibody reaction or trigger stimuli and reduce the frequency of asthma exacerbations. They produce more

sustained symptomatic relief than any bronchodilator and mast cell stabilizer. Systemic steroids are used in both severe chronic asthma and in acute emergency of asthma (*status asthmaticus*).

The inhaled steroids suppress asthma by a topical anti-inflammatory action without causing any systemic side effects. They reduce the bronchial hyperreactivity and increase the peak expiratory flow rate in asthmatic patients. They are not effective during an acute attack or in status asthmaticus. Side effects are sore throat, hoarseness of voice, dysphonia, oropharyngeal candidiasis.

Leukotriene Pathway Inhibitors:

Apart from histamine, leukotrienes liberated during inflammation are more powerful bronchoconstrictor and are longer acting. Leukotrienes also increase bronchial mucus secretion, increase vascular permeability, bronchoconstriction and increased bronchial reactivity. All the leukotrienes are derived from 5- lipoxygenase pathway of arachidonic acid and are synthesized by a variety of inflammatory cells in the airways e.g. eosinophils, mast cells, basophils and macrophages. The drug, **montelukast** and **zafirlukast** are available for the treatment of asthmatic patients.

NASAL DECONGESTANTS:

These are α agonists which on topical application as dilute solution (0.05–0.1%) produce local vasoconstriction. The imidazoline compounds- naphazoline, xylometazoline and oxymetazoline are relatively selective α_2 agonist (like clonidine). They have a longer duration of action (12 hours) than ephedrine. They may cause initial stinging sensation (specially naphazoline). Regular use of these agents for long periods should be avoided because mucosal ciliary function is impaired: atrophic rhinitis and anosmia can occur due to persistent vasoconstriction. They can be absorbed from the nose and produce systemic effects, mainly CNS depression and rise in BP. These drugs should be used cautiously in hypertensives and in those receiving MAO inhibitors.

Pseudophedrine: A stereoisomer of ephedrine; causes vasoconstriction, especially in mucosae and skin, but has fewer CNS and cardiac effect and is a poor bronchodilator (little β_2 agonistic activity). It has been used orally as a decongestant of upper respiratory tract and nose. Combined with antihistaminics, mucolytics, antitussives and analgesics, it is believed to afford symptomatic relief in common cold, allergic rhinitis, and upper respiratory tract infections.

Phenylpropanolamine (PPA): Being chemically and pharmacologically similar to ephedrine, PPA causes vasoconstriction and has some amphetamine like CNS effects, including suppression of hunger. It was included in a large number of oral cold/decongestant combination remedies, and in USA it was used as an appetite suppressant as well. Following reports and case control studies associating PPA use with haemorrhagic stroke and concerns regarding its potential to precipitate behavioural/psychiatric disturbances, many countries, led by USA, prohibited the sale of PPA containing medicines decades back.

ANALEPTICS (Respiratory stimulants):

These are drugs which stimulate respiration and can have resuscitative value in coma or fainting. They do stimulate respiration in subconvulsive doses, but margin of safety is narrow; the patient may get convulsions while still in coma. Mechanical support to respiration and other measures to improve circulation are more effective and safe. The role of analeptics in therapeutics is very limited. Situations in which they may be employed are:

- (a) As an expedient measure in hypnotic drug poisoning until mechanical ventilation is instituted.
- (b) Suffocation on drowning, acute respiratory insufficiency.
- (c) Apnoea in premature infant.
- (d) Failure to ventilate spontaneously after general anaesthesia.

However, the overall utility of analeptics is dubious.

Doxapram It acts by promoting excitation of central neurones. At low doses it is more selective for the respiratory centre than other analeptics. Respiration is stimulated through carotid and aortic body chemoreceptors as well. Falling BP rises. Continuous i.v. infusion of doxapram may abolish episodes of apnoea in premature infant not responding to theophylline.

DRUGS ACTING ON THE GASTROINTESTINAL TRACT

Antiulcer agents

PEPTIC ULCER: Peptic ulcer occurs in that part of the gastrointestinal tract (g.i.t.) which is exposed to gastric acid and pepsin, i.e. the stomach and duodenum. The etiology of peptic ulcer is not clearly known. It results probably due to an imbalance between the *aggressive* (acid, pepsin, bile and *H. pylori*) and the *defensive* (gastric mucus and bicarbonate secretion, prostaglandins, nitric oxide, high mucosal blood flow, innate resistance of the mucosal cells) factors. A variety of psychosomatic, humoral and vascular derangements have been implicated and the importance of *Helicobacter pylori* infection as a contributor to ulcer formation and recurrence has been recognized.

Classification of antiulcer drugs:

1. Reduction of gastric acid secretion

(a) ***H₂ antihistamines:*** Cimetidine, Ranitidine, Famotidine, Roxatidine

(b) ***Proton pump inhibitors:*** Omeprazole, Esomeprazole, Lansoprazole, Pantoprazole, Rabeprazole, Dextrabeprazole

(c) ***Anticholinergic drugs:*** Pirenzepine, Propantheline, Oxyphenonium

(d) ***Prostaglandin analogue:*** Misoprostol

2. Neutralization of gastric acid (Antacids)

(a) ***Systemic:*** Sodium bicarbonate, Sod. citrate

(b) ***Nonsystemic:*** Magnesium hydroxide, Mag. trisilicate, Aluminium hydroxide gel, Magaldrate, Calcium carbonate

3. Ulcer protectives: Sucralfate, Colloidal bismuth subcitrate (CBS)

4. Anti-*H. pylori* drugs: Amoxicillin, Clarithromycin, Metronidazole, Tinidazole, Tetracycline

H2 ANTAGONISTS:

These are the first class of highly effective drugs for acid-peptic disease, but have been surpassed by proton pump inhibitors (PPIs). Four H2 antagonists cimetidine, ranitidine, famotidine and roxatidine are available in India.

Pharmacological actions:

1. H2 blockade: Cimetidine and all other H2 antagonists block histamine-induced gastric secretion, cardiac stimulation (prominent in isolated preparations, especially in guinea pig), uterine relaxation (in rat) and bronchial relaxation (H2 blockers potentiate histamine induced bronchospasm).

2. Gastric secretion: The only significant *in vivo* action of H2 blockers is marked inhibition of gastric secretion. All phases (basal, psychic, neurogenic, gastric) of secretion are suppressed dose-dependently. Secretary responses to not only histamine but all other stimuli (ACh, gastrin, insulin, alcohol, food) are attenuated. The volume, pepsin content and intrinsic factor secretion are reduced, but the most marked effect is on acid. The usual ulcer healing doses produce 60–70% inhibition of 24 hr acid output. The H2 blockers have antiulcerogenic effect. Gastric ulceration due to stress and drugs (NSAIDs, cholinergic, histaminergic) is prevented. They do not have any direct effect on gastric or esophageal motility or on lower esophageal sphincter (LES) tone.

Pharmacokinetics:

Cimetidine is adequately absorbed orally, though bioavailability is 60–80% due to first pass hepatic metabolism. Absorption is not interfered by presence of food in stomach. It crosses

placenta and reaches milk, but penetration in brain is poor because of its hydrophilic nature. About 2/3 of a dose is excreted unchanged in urine and bile, the rest as oxidized metabolites. The elimination $t_{1/2}$ is 2–3 hr.

Adverse effects:

Cimetidine is well tolerated by most patients: adverse effects occur in < 5%. These are generally mild.

- Headache, dizziness, bowel upset, dry mouth, rashes.
- Cimetidine (but not other H₂ blockers) has antiandrogenic action (displaces dihydrotestosterone from its cytoplasmic receptor), increases plasma prolactin and inhibits degradation of estradiol by liver. High doses given for long periods have produced gynaecomastia, loss of libido, impotence and temporary decrease in sperm count.
- Transient elevation of plasma aminotransferases; but hepatotoxicity is rare.

Ranitidine: A nonimidazole (has a furan ring) H₂ blocker, it has several desirable features compared to cimetidine:

- About 5 times more potent than cimetidine. Though its pharmacokinetic profile and $t_{1/2}$ of 2–3 hr is similar to cimetidine, a longer duration of action with greater 24 hr acid suppression is obtained clinically because of higher potency.
- No antiandrogenic action, does not increase prolactin secretion or spare estradiol from hepatic metabolism—no effect on male sexual function or gynaecomastia.
- Lesser permeability into the brain: lower propensity to cause CNS effects. In fact, little effect outside g.i.t. has been observed.
- Overall incidence of side effects is lower: headache, diarrhoea/constipation, dizziness have an incidence similar to placebo.

Uses:

The H₂ blockers are used in conditions in which it is profitable to suppress gastric acid secretion.

Used in appropriate doses, all available agents have similar efficacy.

1. *Duodenal ulcer*
2. *Gastric ulcer*
3. *Stress ulcers and gastritis*
4. *Zollinger-Ellison syndrome*
5. *Gastroesophageal reflux disease (GERD)*

PROTON PUMP INHIBITORS (PPIs):

Omeprazole: It is the prototype member which inhibits the final common step in gastric acid secretion. The PPIs have overtaken H₂ blockers for acid-peptic disorders. The only significant pharmacological action of omeprazole is dose dependent suppression of gastric acid secretion; without anticholinergic or H₂ blocking action. It is a powerful inhibitor of gastric acid: can totally abolish HCl secretion, both resting as well as that stimulated by food or any of the secretagogues, without much effect on pepsin, intrinsic factor, juice volume and gastric motility. Omeprazole is inactive at neutral pH, but at pH < 5 it reacts covalently with H⁺K⁺ATPase enzyme and inactivate it irreversibly, especially when two molecules of omeprazole react with one molecule of the enzyme. Acid secretion resumes only when new H⁺K⁺ATPase molecules are synthesized (reactivation half time 18 hours).

Pharmacokinetics: All PPIs are administered orally in enteric coated form to protect them from molecular transformation in the acidic gastric juice. The e.c. tablet or granules filled in capsules should not be broken or crushed before swallowing. Oral bioavailability of omeprazole

is ~50% due to acid lability. Bioavailability of all PPIs is reduced by food; they should be taken in empty stomach, followed 1 hour later by a meal to activate the H⁺K⁺ ATPase and make it more susceptible to the PPI. Omeprazole is highly plasma protein bound, rapidly metabolised in liver (plasma t_{1/2} ~1 hr). The metabolites are excreted in urine.

Uses:

1. *Peptic ulcer:*
2. *Bleeding peptic ulcer:*
3. *Stress ulcers:*
4. *Gastroesophageal reflux disease (GERD)*
5. *Zollinger-Ellison syndrome*

Adverse effects: PPIs produce minimal adverse effects. Nausea, loose stools, headache, abdominal pain, muscle and joint pain, dizziness are complained by 3–5%. Rashes (1.5% incidence), leucopenia and hepatic dysfunction are infrequent. No harmful effects of PPIs during pregnancy are known.

Pantoprazole: It is similar in potency and clinical efficacy to omeprazole, but is more acid stable and has higher oral bioavailability. It is also available for i.v. administration; particularly employed in bleeding peptic ulcer and for prophylaxis of acute stress ulcers. Affinity for cytochrome P450 is lower than omeprazole or lansoprazole: risk of drug interactions is minimal.

Rabeprazole: This newer PPI is claimed to cause fastest acid suppression. Due to higher pK_a, it is more rapidly converted to the active species. However, potency and efficacy are similar to omeprazole.

PROSTAGLANDIN ANALOGUE:

PGE₂ and PGI₂ are produced in the gastric mucosa and appear to serve a protective role by inhibiting acid secretion and promoting mucus as well as HCO₃⁻ secretion. In addition, PGs inhibit gastrin release, increase mucosal blood flow and probably have an “cytoprotective” action. However, the most important to be their ability to reinforce the mucus layer covering gastric and duodenal mucosa.

Natural PGs have very short t_{1/2}. *Misoprostol* is a longer acting synthetic PGE₁ derivative which inhibits acid output dose dependently. However, reduction in 24 hour acid production is less than H₂ blockers because of shorter duration of action (~3 hr.) Ulcer healing rates comparable to cimetidine have been obtained in 4–8 weeks, but misoprostol is poorer in relieving ulcer pain. Some patients may even complain of increased pain during the first week of therapy.

Adverse effects: Major problems in the use of misoprostol are—diarrhoea, abdominal cramps, uterine bleeding, abortion, and need for multiple daily doses. Patient acceptability is poor.

Uses: The primary indication of misoprostol is the prevention and treatment of NSAID associated gastrointestinal injury and blood loss. However, it is seldom employed now because PPIs are more effective, more convenient, better tolerated and cheaper.

ANTACIDS:

These are basic substances which neutralize gastric acid and raise pH of gastric contents. Antacids do not decrease acid production. The potency of an antacid is generally expressed in terms of its *acid neutralizing capacity* (ANC), which is defined as number of mEq of 1N HCl that are brought to pH 3.5 in 15 min (or 60 min in some tests) by a unit dose of the antacid preparation. This takes into consideration the rate at which the antacid dissolves and reacts with

HCl. This is important because a single dose of any antacid taken in empty stomach acts for 30–60 min only, since in this time any gastric content is passed into duodenum. Taken with meals antacids may act for at the most 2–3 hr.

Systemic Antacids:

Sodium bicarbonate: It is water soluble, acts instantaneously, but the duration of action is short.

It is a potent neutralizer, pH may rise above 7. However, it has several demerits:

- (a) Absorbed systemically: large doses will induce alkalosis.
- (b) Produces CO₂ in stomach → distention, discomfort, belching, risk of ulcer perforation.
- (c) Increases Na⁺ load: may worsen edema and CHF.

Use of sod. bicarbonate is restricted to casual treatment of heartburn. It provides quick symptomatic relief. Other uses are to alkalinize urine and to treat acidosis.

Nonsystemic Antacids:

Mag. hydroxide has low water solubility: its aqueous suspension (milk of magnesia) has low concentration of OH⁻ ions and thus low alkalinity. However, it reacts with HCl promptly and is an efficacious antacid (1 g → 30 mEq HCl). Rebound acidity is mild and brief. MILK OF MAGNESIA 0.4 g/5 ml suspension: 5 ml neutralizes 12 mEq acid.

Magnesium trisilicate has low solubility and reactivity; 1 g can react with 10 mEq acid, but in clinical use only about 1 mEq is neutralized. About 5% of administered Mg is absorbed systemically— may cause problem if renal function is inadequate. All Mg salts have a laxative action by generating osmotically active MgCl₂ in the stomach and through Mg²⁺ ion induced cholecystokinin release. Soluble Mg salts are used as osmotic purgatives.

Aluminium hydroxide gel It is a bland, weak and slowly reacting antacid. On keeping it slowly polymerizes to variable extents into still less reactive forms. Thus, the ANC of a preparation

gradually declines on storage. Also, the product from different manufacturers may have differing ANC's; usually it varies from 1–2.5 mEq/g. Thus, 5 ml of its suspension may neutralize just 1 mEq HCl. As such, little worthwhile acid neutralization is obtained at conventional doses. use.

Magaldrate It is a hydrated complex of hydroxymagnesium aluminate that initially reacts rapidly with acid and releases alum. hydrox. which then reacts more slowly. It is a good antacid with prompt and sustained neutralizing action.

Calcium carbonate It is a potent and rapidly acting acid neutralizer ($1\text{ g} \rightarrow 20\text{ mEq HCl}$), but ANC of commercial preparations is less and variable due to differing particle size and crystal structure. Though it liberates CO_2 in the stomach at a slower rate than NaHCO_3 , it can cause distention and discomfort. The Ca^{2+} ions are partly absorbed.

Uses: Antacids are no longer used for healing peptic ulcer, because they are needed in large and frequent doses, are inconvenient, can cause acid rebound and bowel upset and have poor patient acceptability. Antacids are now employed only for intercurrent pain relief and acidity, mostly self-prescribed by the patients as over the counter preparations.

ULCER PROTECTIVES:

Sucralfate: It is a basic aluminium salt of sulfated sucrose. Sucralfate polymerizes at $\text{pH} < 4$ by cross linking of molecules, assuming a sticky gel-like consistency. It preferentially and strongly adheres to ulcer base, especially duodenal ulcer; has been seen endoscopically to remain there for ~ 6 hours. Surface proteins at ulcer base are precipitated, together with which it acts as a physical barrier preventing acid, pepsin and bile from coming in contact with the ulcer base. Dietary proteins get deposited on this coat, forming another layer. Sucralfate has no acid neutralizing action, but delays gastric emptying—its own stay in stomach is prolonged.

Sucralfate is minimally absorbed after oral administration. Its action is entirely local. It promotes healing of both duodenal and gastric ulcers. Healing efficacy has been found similar to cimetidine at 4 weeks.. However, sucralfate is infrequently used now because of need for 4 large well-timed daily doses and the availability of simpler and more effective H₂ blockers/PPIs.

Dose: The ulcer healing dose of sucralfate is 1 g taken in empty stomach 1 hour before the 3 major meals and at bed time for 4–8 weeks.

Colloidal bismuth subcitrate (CBS):

It is a colloidal bismuth compound; water soluble but precipitates at pH < 5. It is not an antacid but heals 60% ulcers at 4 weeks and 80–90% at 8 weeks. The mechanism of action of CBS is not clear; probabilities are:

- May increase gastric mucosal PGE₂, mucus and HCO₃⁻ production.
- May precipitate mucus glycoproteins and coat the ulcer base.
- May detach and inhibit *H.pylori* directly.

BP 507 P. PHARMACOLOGY-II (Practical)
4Hrs/Week

1. Introduction to *in-vitro* pharmacology and physiological salt solutions.
2. Effect of drugs on isolated frog heart.
3. Effect of drugs on blood pressure and heart rate of dog.
4. Study of diuretic activity of drugs using rats/mice.
5. DRC of acetylcholine using frog rectus abdominis muscle.
6. Effect of physostigmine and atropine on DRC of acetylcholine using frog rectus abdominis muscle and rat ileum respectively.
7. Bioassay of histamine using guinea pig ileum by matching method.
8. Bioassay of oxytocin using rat uterine horn by interpolation method.
9. Bioassay of serotonin using rat fundus strip by three point bioassay.
10. Bioassay of acetylcholine using rat ileum/colon by four point bioassay.
11. Determination of PA₂ value of prazosin using rat anococcygeus muscle (by Schilds plot method).
12. Determination of PD₂ value using guinea pig ileum.
13. Effect of spasmogens and spasmolytics using rabbit jejunum.
14. Anti-inflammatory activity of drugs using carrageenan induced paw-edema model.
15. Analgesic activity of drug using central and peripheral methods

PHARMACOLOGY-II

EX NO:1

Introduction to *In-vitro* pharmacology and physiological salt solutions.

Aim: To study the Introduction about In-Vitro Pharmacology and Physiological salt solutions.

Introduction:

“In vitro” is a latin word that means “**within the glass**” Therefore the studies which are done outside the living organism, inside glass (test tubes or petridishes) are known as In vitro studies.

It is the experiment or observations done on the tissue outside of the living organism in a controlled environment ,usually using petridishes and testtubes.

In vitro processes ,conditions are artificial and they are reconstructions of In vivo environments.Artificial conditions are formed by mixing the necessary components and reagents under controlled conditions inside a glassware in the laboratory .

In vitro methods are widely used in Pharmaceutical industry to produce large scale pharamaceuticals using microorganism due to ease of production and economic benefits.

Advantages of in-vitro studies :

In vitro studies permit a species-specific.

simpler, more convenient

more detailed analysis

In vitro studies replacing studies in whole animals.

It is less expensive and provides quicker results.

Definition:

Estimation of potency of an active ingredient in unit quantity of preparation is detection and measurement of concentration of substance preparation using biological method is known as bioassay.

Principle of Bioassay:

The basic principle of bioassay is to compare the test substance with internal standards of the same and find out how much test substance is required to produce same biological effect that are produced by the standard.

Methods of bioassay:

1.Quantal assay

2.Graded response assay

1.Quantal assay :

In this bioassay the dose of the standard and that of the unknown which provide the predominant or all or none response is measured and their potency ratio is compared.

Eg: digitalis induced cardiac arrest is in guinea pig or cat.

2.Graded response assay:

These are called graded response assay because the response to varying doses of drugs are graded and measured repeatedly of acetylcholine on frog rectus abdominal muscle.

2.1.Matching bioassay:

It is used when the test sample is too low. In this method a curve of which match is response with dose of standard is found by trial and error. From this the potency of unknown test solution can be calculated.

2.2. Bracketing Bioassay:

It is also used when the test sample is too small the observed test response with the drug is tracked between the one higher and one lower response of standard. The strength of the unknown can be found by sample interpolation of this tracked response on the dose axis.

2.3. Interpolation method:

It is based on the principle of log response. In the method LDR curve of the standard drug is obtained at 1st later 2nd and 3rd response of the unknown which fall in between linear portion of LDR curve are obtained by trial and error. Then interpolation of this response of log dose axis taking the antilog the concentration of this response can be found.

2.4. Multiple point bioassay:

a.Three point bioassay:

The response of standard drug and one response is due to the test sample are taken into consideration. The test response should be intermediate between the 2 responses of the standard.

b.Four point bioassay:

Two response of standard drug and two response of test drug are made use should be linear portion of the concentration curve and also the ration between the dose should be perfectly 1:2 the solution of test response are recorded in the random fashion.

Instruments used in In-Vitro Pharmacology

1.Dale's organ bath or isolated organ bath.

- a.Inner glass tube or organ bath containing PSS and tissue
- b.Connected reservoir through polyethylene or rubber tube.
- c.An outer glass or filled with water
- d.Kymograph drum

2.Sherington's research kymograph:

- a.Base hoof (Legs)
- b.Slide hoof
- c.Gear rods
- d.Drum cylinder.

3.Lever

It is the device by virtue of which response of isolated tissue can be recorded and magnified.

- a.Fulcrum
- b.Stylus

Magnification:

The fulcrum should be placed that there is some magnification of the actual concentration. In order to achieve this distance between the writing point and the fulcrum and point of attachment of tissue.

Name of tissue magnification:

- (i) Guinea pig ileum 5-10 times.
- (ii) Rat uterus 4-6 times.
- (iii) Frog rectus abdominus muscle 10 times.
- (iv) Rat fundus stripe 15 times.

Different types of levers:

- 1.Simple lever
- 2.Frontal writing lever
- 3.Starling's heart lever

- 4.universal lever
- 5.Arterial cannula
- 6.venus cannula
- 7.Tracheal cannula
- 8.Bull dog clamp
- 9.Rat holder
- 10.syringes

Physiological salt solutions

The ionic requirements and nutritional supply can be provided by using the suitable solution ,commonly known as physiological salt solution. Also called as PSS /Ringer solution Its composition is such that it provides an artificial media resembling the inorganic composition of blood plasma together with a buffer mechanism to maintain the optimum pH about 7.0 to 7.2 and glucose to facilitate tissue metabolism.

Commonly used PSS

- 1.**Frog ringer-** (For heart,rectus abdominis and other preparations of frog)
- 2.**Tyrode** (For guinea pig ileum,rat ileum,rabbit ileum etc)
- 3.**De jalon** (For rat uterus)
- 4.**Kreb's Solution** (for rat fundus strip,Tracheal preparations, Vas deferens)etc

The PSS should:

It Maintains tissue outside the animal body .

Select PSS in which tissue last longer.

Prepare the solution with the help of distilled or double distilled or deionised water.

Prepare fresh solution.

Ingredients	Concentration in gms/l			
	Frog ringer	Tyrode	Kreb's bicarbonate	De jalon
NaCl	6.5	8.0	5.9	9.0
KCl	0.14	0.2	0.35	0.350
CaCl ₂	0.12	0.18	0.28	0.003
NaH ₂ PO ₄	0.05	0.1	-	-
KH ₂ PO ₄	-	-	0.16	-
MgSO ₄	-	-	0.11	-
MgCl ₂	-	0.1	-	-

Glucose	1.5	1.0	2.0	0.5
NaHCO ₃	0.4	1.0	2.1	0.5

PURPOSE OF EACH INGREDIENT

1.	Sodium Chloride (NaCl)	To maintain iso osmolarity, isotonicity, excitability and contractility of the preparation
2.	Potassium Chloride (KCl)	To maintain ionic balance
3.	Calcium Chloride (CaCl ₂)	To maintain the contractility of the preparation
4.	Sodium bicarbonate (NaHCO ₃)	To provide alkaline pH
5.	Glucose	To provide energy
6.	Sodium or potassium	Act as the buffer
7.	Di hydrogen phosphate	To stabilize the preparation
8	Sulphate	To stabilize the preparation and hence to reduce the spontaneous activity

Report:

Effect of drugs on isolated frog heart

EX NO:2

Aim: To study the effect of drugs (inotropic and chronotropic actions) on perfused frog heart.

Principle:

Drugs may influence the rate (chronotropy) and force (inotropy) of contraction of the heart. An increase in the heart rate is called a “positive chronotropic” response, while a “negative chronotropic” response is a decrease in the heart rate. Similarly, an increase in the force of contraction is called a ‘positive inotropic’ response and a decrease in the force of contraction is called a ‘negative inotropic’ response.

Sympathomimetic amines such as adrenaline and noradrenaline produce positive inotropic and positive chronotropic response, whereas parasympathomimetics such as acetylcholine produce negative inotropic and negative chronotropic response.

Requirements:

Animal : frog

Apparatus : frog's ringer solution, reservoir, tubing, screw clip, syringe, cannula, clamp, boss-head, thread, syringe and needle.

Drugs : Adrenalin (stock solution 10 µg/ml)
Noradrenaline (stock solution 10 µg/ml)
Acetylcholine (stock solution 10 µg/ml)
Calcium chloride (stock solution 10 µg/ml)
Potassium chloride (stock solution 10 µg/ml)

Physiological solution : Frog ringer

Procedure:

1. Pith the frog and pin it to the frog board.
2. Give a mid line incision on the abdomen. Remove the pectoral girdle and expose the heart.
3. Carefully remove the pericardium and put a few drops of frog ringer over the heart.

4. Trace the inferior vena cava, put a thread around it and give a small cut in order to insert the venous cannula which is in turn connected to a perfusion bottle containing frog ringer. Insert a cannula in the vein and tie the thread to assure the cannula in place.
5. Give a small cut in one of the aortae for the perfusate to come out.
6. Adjust a proper venous pressure of 2-4 cm by altering the height of perfusion bottle. The effective venous pressure is the height in cms from level of the venous cannula and the ringer level in the perfusion bottle. Use of marriott's bottle helps in attaining the constant pressure. Start the perfusion by opening screw clamp attached to the tube.
7. Pass a thin pin hook through the tip of the ventricle, and with the help of a fine thread attached to the hook, tie it to the free limb of the universal lever, which is fixed to a stand. Adjust proper tension and magnification by altering the height of the lever. Record the normal contraction of the heart on the smoked drum.
8. Inject 0.1, 0.2, 0.5 and 1 ml of the stock solution of each drug in a sequential order and note the change in the rate and amplitude of contraction. Keep at least 5 min gap between the administration of each dose of the drug. The drug is administered by injecting the drug into the perfusion tube very close to the venous cannula. Take precautions to avoid any leakage of the drug from the tube, and the injection of air bubbles.
9. Label and fix the tracing with the fixing solution.

Observation:

Report:

EX NO:3

EFFECT OF DRUGS ON NORMAL AND HYPODYNAMIC PERFUSED FROG HEART

AIM: To study the effect of drugs on normal and hypodynamic frog heart.

Principle: The myocardial contraction of normal and hypodynamic frog heart takes place according to Starling's law of heart. According to this law force of systolic contraction is directly proportional to the fibre length in diastole. Since systolic contraction represents cardiac output and the fibre length in diastole indicates venous pressure, the law indicates that cardiac output (i.e. stroke volume) is directly related to venous return or venous pressure during diastole.

When the cardiac musculature fails to obey this relationship as in failing heart (i.e. congestive heart failure) there will be decrease in stroke volume (cardiac output), incomplete emptying of the ventricles during systole and enlargement of heart size due to residual blood in the heart at the end of systolic contraction. When the heart is in this state, i.e. inability to contract to physiological normal it is said to be hypodynamic heart.

Experimentally hypodynamic heart can be produced by perfusing the heart with Ringer containing less quantity of Calcium as this bivalent ion is essential for myocardial contraction.

Requirements:

Animal : frog

Drugs : Digitalis (Digoxin stock solution 50 µg/ml)

Calcium chloride (stock solution 100 µg/ml)

Physiological solution Normal frog Ringer and frog Ringer containing $\frac{1}{4}$ CaCl₂.

Procedure:

1. Set up the perfusion of frog heart with normal frog Ringer solution as described in the earlier experiment.
2. Record the effects of (0.1, 0.2, 0.4, and 0.5 ml) digoxin and CaCl₂ (0.1, 0.2, 0.4, and 0.5 ml). Note the dose that gives an adequate response.
3. Replace the perfusion fluid with modified Ringer containing only $\frac{1}{4}$ th the Calcium chloride as compared to that of normal Ringer. Note the change in the pattern of recording of the heart.
4. When the heart is depressed markedly in presence of modified Ringer, administer digoxin (0.1, 0.2, 0.4 and 0.5 ml) and CaCl₂ (0.1, 0.2, 0.4 and 0.5 ml). Note the change in contractility.
5. Fix the tracing and compare the responses of these drugs in normal and hypodynamic heart.

Observation:**Report:**

EX NO:4

Effect of drugs on blood pressure and heart rate of dog

Aim: To study the effect of drugs on **blood pressure** and heart rate of dog.

Principle: The arterial blood pressure is defined as the pressure exerted by the blood on the walls of the blood vessels. Therefore, $\text{blood pressure} = \text{cardiac output} \times \text{peripheral resistance}$. The heart and the blood vessels are under the control of autonomic nervous system.

Both sympathetic and parasympathetic nerves supply the heart. Parasympathetic innervation is through the vagus supply the heart. Parasympathetic innervation is through the vagus whereas the sympathetic nerve supply to the heart comes from fibres arising from stellate or inferior cervical ganglion. The nervous supply to the blood vessels are principally from the sympathetic system. In general, sympathetic stimulation (administration of adrenaline and noradrenaline) increases cardiac output and resistance to flow leading to an increased blood pressure.

On the other hand, parasympathetic stimulation (administration of acetylcholine) decreases cardiac output which lowers the blood pressure. Drugs which increase the blood pressure are called pressor agents, and those decrease are called .

Requirements:

Animal – Dog (6-8 kg)

Anaesthetic pentobarbitone sodium (45 mg /kg ,iv ;prepare a stock solution containing 45mg/ml of the drug and per kg of body weight.

Drugs: adrenaline, noradrenaline ,isoprenaline, acetylcholine (all 100 mg/ml stock solution), normal saline ,and sodium citrate (10% w/v).

Equipment: Artery cannula, venous cannula ,dog operating table, research kymograph (big), mercury manometer and surgical equipment.

Procedure:

1. Anaesthetise the dog with pentobarbitone (45 mg/kg) given intravenously.
2. Cannulate the femoral vein and connect it to a burette containing saline. Femoral vein cannulation is used for drug administration.

3. Cannulate carotid artery and mount the blood pressure using mercury manometer.
4. Record the base –line mean blood pressure response. Note the heart rate.
5. Inject 3 or 5 $\mu\text{g/kg}$ adrenaline through the femoral venous cannula. Note the sequence of the response, *i.e.* rise in blood pressure, heart rate, the vagal notch, blood pressure falling below the base line and recovery to Pre-drug base line. Wait for 5-10 min.
6. similarly administer noradrenaline, isoprenaline and acetylcholine, one after the other. Give sufficient gap (5-10 min) between the effects of two drugs.

EX NO:5

Study of diuretic activity of drugs using rats/mice.(Lipschitz test)

Aim: To study the effects of various drugs (diuretics) on the output of urine.

Principle: Diuretics are the compound which increases the flow of urine. Normal urine output in rats is very small (1-2 ml/rat/day).Hence to get the measurable quantity the animals are first hydrated.The urine output is increased after administration of diuretics like urea,hydroflumethiziade and frusemide.Increase in volume of urine is measured with the help of measuring cylinder and compared with the normal urine output.

Requirement:

Rats,metabolic cages,graduated measuring cylinder.

Drugs and solutions: Normal saline(0.9%)

Urea (900 mg/kg;oral)

Hydroflumethiazide(1mg/kg;oral)

Frusemide(5mg/kg;oral)

Procedure:

- 1.albino rats (150-200 g) are fasted (deprived of food and water) overnight and saline(25ml/kg) is administered orally with the help of oral feeding cannula.
- 2.Those animals are divided into four groups containing three rats in each as follows:
 - (i) Ist group- only normal saline (N.Saline)
 - (ii) IInd group- saline + Urea (900 mg/kg; oral)
 - (iii) IIIrd group-saline +hydroflumethiazide(1mg/kg;oral)
 - (iv) IVth group-saline +frusemide(5mg/kg ;oral)
- 3.After administration of drugs animals are placed in the four different metabolic cages.
- 4.Urine is collected in a measuring cylinder.
- 5.Time,when the first drop of urine is collected in a cylinder for each group is noted and the volume is recorded at intervals of 15 min for 3-4 hrs.

6. The difference in the volume collected at different time interval and total volume can be compared with various diuretics.

EX NO:6

DRC of acetylcholine using frog rectus abdominis muscle

Aim: To record a concentration response curve of acetylcholine using rectus abdominis muscle preparation of frog.

Principle:

Dose (concentration)-response curves demonstrate graded responses to drugs or agonists where an increase in response is recorded with a subsequent increase in the dose or the concentration of the drug. The dose-response curve is sigmoid or S-shaped. The first part (25% of graph) of the curve has poor discrimination between the doses, whereas the middle portion of the curve shows greater sensitivity to different concentrations, and the responses to increasing concentrations are linearly differentiated. The last of the curve (plateau) shows the ceiling effect where no more increase in the response is seen with further increase in the dose.

When the doses are increased in geometric progression (logarithmic intervals) and the response is plotted against logarithms of doses, the relationship is called log dose-response curve.

Rectus abdominis muscle is a skeletal muscle, and the response of acetylcholine is described as nicotinic response.

Requirements:

Animals : Frog

Drugs : Acetylcholine stock solution (1 mg/ml)

Physiological solution : Frog Ringer

Procedure

1. Pith or stun the frog and lay it on its back on the frog-dissecting board. Pin the four limbs.
2. Remove the skin on the abdomen and expose the rectus abdominis muscle,
3. Cut and prepare two rectus muscle preparations from each frog. Tie a thread to the top and bottom of each muscle preparation before detaching the muscle from the body of the frog.
4. Mount the preparation in up-right position in the organ bath containing frog Ringer solution under a tension of 1 g. There is no need of maintaining the bath temperature since it is an amphibian tissue preparation. Bubble the organ with air.

5. Relax the tissue for 45 min, during which period wash the tissue with fresh quantum of ringer for at least four times.
6. Record the concentrations due to acetylcholine using either simple sideways or frontal writing lever. Ninety second contact time and a total 5 min time cycle may be used for proper recording of the responses.
7. Record at least four responses to increasing doses of acetyl choline or till you get the maximum response. The maximum response is achieved if one gets same or slightly less response with a higher concentrations. Properly label the graph, put the date, your name, and fix the tracing with the help of fixing solution.
8. Measure the height of the response (mm) and draw a dose (concentration)- response graph.

REPORT:

EX NO:7

Effect of physostigmine on DRC of acetylcholine using frog rectus abdominis muscle and rat ileum respectively.

Aim: To record the effect of Physostigmine (eserine) on the concentration-response curve of acetylcholine using rat ileum preparation.

Principle:

Rat colon is an intestinal smooth muscle. Ach causes the contraction of the muscle by acting on muscarinic receptors. The spontaneous contraction of muscle preparation can be reduced by calcium level of physiological salt solution and maintain the water bath at room temperature. The muscle preparation obtained from a starved rat gives a stable preparation. Physostigmine increases the levels of Ach.

Physostigmine is an anticholinesterase substance and it inhibits the metabolic breakdown of acetylcholine. As a result the action of acetylcholine is potentiated. The concentration response curve of acetylcholine will be shifted to the left in the presence of physostigmine.

Requirements:

Animal – frog

Drugs – Acetylcholine stock solution (1 mg/ml), Physostigmine stock solution (1 mg/ml)

Physiological solution – modified Ringer with less calcium

Procedure:

1. Step 1 to 6 are same as previous experiment
2. Record a concentration response curve of acetylcholine using at least four doses.
3. Add physostigmine (2 µg/ml) to the reservoir containing frog Ringer and irrigate the tissue with eserine Ringer 30 min.
4. Repeat the concentration-response curves of acetylcholine in the presence of physostigmine.
5. Label and fix both the concentration – response curves.
6. Plot both the concentration – response curves of acetylcholine, i.e. one in the absence and the other in the presence of physostigmine. Note the potentiation in the response of acetylcholine.

Observation:

Report:

EX NO:8

Effect of atropine on DRC of acetylcholine using frog rectus abdominis muscle and rat ileum respectively.

Aim: To record the concentration-response curve of acetylcholine and its modification by atropine using rat ileum preparation.

Principle:

Rat colon is an intestinal smooth muscle. Acetylcholine causes the contractions of the smooth muscle by acting on muscarinic receptors. Atropine blocks muscarinic receptors in the smooth muscle. Therefore, atropine blocks acetylcholine induced contractions in rat colon. The concentration response curve of acetylcholine will be shifted to the right in the presence of atropine. The nature of antagonism is of competitive type.

The spontaneous contractions of the preparations can be reduced by reducing the calcium content in physiological solution and maintaining the bath at room temperature ($23 \pm 2^{\circ}$ C). The muscle (colon) preparation obtained from an unstarved rat gives more stable contractions.

Requirements:

Animal : Rat (150-200g)

Drugs : Acetyl choline stock solution (1mg/ml), Atropine stock solution (1 mg/ml)

Physiological solution: Modified Ringer (contains less calcium)

Procedure:

1. Sacrifice the animal by cervical dislocation.
2. Cut open the abdomen and identify the colon. The right flexure, i.e. the subhepatic region of the colon where the ascending colon turns to become transverse colon, is cut out and placed in a shallow dish containing Modified Ringer's solution.
3. The lumen is gently cleaned and a 3 cm long tissue is mounted in the organ bath containing Modified Ringer's solution (pH 7.4) maintained at 25° C and bubbled with carbogenated air. The preparation is allowed to equilibrate for 45 min under 500g tension.
4. Record the concentration dependent responses due to acetylcholine using frontal writing lever. Contact time 60 sec, and 5 min time cycle are kept for proper recording of the response.

5. Add atropine to the reservoir containing Modified Ringer's solution and irrigate the tissue with atropinised Modified Ringer for 20 min.
6. Repeat the concentration-response curve of acetylcholine in presence of atropine.
7. Label and fix the tracing ,plot the graph as done in the earlier experiments. Calculate EC 50 values and note the nature of antagonism

$$\text{Dose ratio} = \frac{\text{EC 50 after atropine}}{\text{EC 50 before atropine}}$$

Inference:

Report:

EX NO:9

Bioassay of oxytocin using rat uterine horn by interpolation method.

Aim: To record the concentration –response curve of oxytocin using rat uterine horn by interpolation method.

Principle: Oxytocin is a hormone secreted by the posterior pituitary gland. The rat uterine preparation is commonly used for the bioassay of oxytocin. The sensitivity of the uterus to oxytocin depends on the oestrous cycle. The various stages of oestrous cycle can be identified by preparing vaginal smears and observing under microscope. Rat uterus is highly sensitive.

An adult female rat (2-3 months old)has an oestrous cycle of five days. The oestrous cycle is divided into different stages.

1. Dioestrous – characterized by presence of leukocytes in vaginal smear.
2. Proestrous /estrous – characterised by the presence of large number of nucleated epithelial cells.
3. Frank oestrous – Presence of cornified epithelial cells.
4. Meta oestrous or late oestrous –presence of mixture of nucleated ,cornified epithelial cells and leucocytes.

If the rat is not in frank oestrous stage ,it can be induced by the administration of estrogen preparation, stilbestrol (0.1 mg/kg, sc:24 hrs before)

Frank oestrus uterus is highly sensitive to oxytocin and hence preferred for bioassay than the dioestrous uterus which is relatively less sensitive.

Requirements:

Animal : Female rat (120-150 g)

Drugs : Oxytocin ,Stilbestrol

Physiological solution : De jalon

Student organ bath

Procedure :

A. preparation of animal:

1. Examine the vaginal smear under microscope to know about the proper stage of oestrus cycle. If the rat is not in frank oestrus, inject 0.1 mg/kg of stilbestrol and wait for 24 hr.(Vaginal smear is prepared by taking a drop of vaginal wash and putting on the glass slide).

2. If the epithelial cells are present in the smear ,it is said to be in frankoestrous phase.

B). Isolation of tissue:

1. Animal is sacrificed by cervical dislocation.

2. Cut open the pelvic region and expose both the horns of uterus. Separate them gently from the surrounding fatty material and transfer them into a dish containing De jalon's solution. when the rat is in oestrus generally the uterus is fleshy and pink in colour.

3. Then the uterus is cut longitudinally and a tissue portion of 2-3 cm long is taken and both ends are tied with the thread.

C) Mounting the tissue:

1. About 2-3 cm long tissue is mounted in organ bath containing De jalons solution at 32°C along with proper aeration.

2. A tension of about 500 mg (0.5g) is applied and tissue is allowed to equilibrate for 45 min.

D. Recording of the response:

1. Record the DRC for the standard oxytocin solution is taken.

2. Record responses due to 0.1 , 0.2 , or 0.4 ml of the test substance. See that these responses would fall on the linear portion of the concentration –Response curve for the standard solution

3. Label and fix the tracing.

4. Plot the concentration response curve due to standard acetyl choline solution. Measure the heights of the contractions (response) due to different doses (A and B) of test solution .read the corresponding concentration from the standard curve.

EX NO:10

Bioassay of serotonin using rat fundus strip by three point bioassay

Aim: To find out the concentration of the given sample of 5 HT (5-hydroxy tryptamine) or serotonin by three point bioassay using rat fundus strip preparation.

Principle:

Rat fundus is a very sensitive tissue for the study of the action of several naturally occurring substances like 5-hydroxy tryptamine, histamine, acetyl choline and bradykinin. Unlike the intestinal smooth muscle(ileum) this preparation is slow contracting and slow relaxing type. Rat fundus is generally employed for the bioassay of serotonin. The fundus (the upper part of the stomach) is grey in colour and therefore, easily identified from pyloric part (pink in colour). A zig-zag preparation of the fundal strip is prepared so as to expose maximum portion of the tissue to drug.

The tissue is sensitive to 1 ng/ml of serotonin, 0.05-1 ng/ml of histamine and 0.2-0.5 ng/ml of acetyl choline, respectively.

Principle of Three point bioassay: It is a method based on the assumption of dose-response relationship. Log dose response curve is plotted and the dose of the standard producing the same response as produced by the test sample is directly read from the graph so to estimate the potency of the test sample.

In three point bioassay, the DRC of standard, test samples is first obtained from the responses due to graded doses. From the DRC of standard, two standard doses are selected in such a way that they have produced 20% and 80 % of the maximal response respectively and are designated as S1 and S2. The responses of these doses lie on the steepest and straightest part (linear) of the curve. From the DRC of test sample one test dose is selected such that it gives a response which lies in between the two standard responses i.e. it gives a greater response than S1 and a smaller response than S2 and is designated as T.

After selecting the standard and test doses, the bioassay is performed by recording the standard and test responses in a randomized fashion. The pattern of addition of doses is S1 S2 T; S2, T, S1 and T, S1, S2 in 3 successive cycles. The mean values of height of the contraction for all the 3 doses are calculated and are used in plotting the graph so as to estimate the potency of the test sample.

Advantages:

More precision

Reliability.

Requirements:

Animal : Rats (150-200 g ,overnight fasted)

Drug : serotonin (Stock solution 10 µg/ml)

Physiological solution : Krebs solution

Procedure :

1. Sacrifice the rat by a blow on the head and carotid bleeding.
2. Cut open the abdomen and expose the stomach.
3. Identify the fundus of the stomach(upper part) .Incise it from the junction of pyloric part and put it in the dish containing krebs solution.
4. Incise the fundus from the lesser curvature and open it longitudinally. Give alternate zig zag cuts to make a fundal strip preparation. Tie both the ends with the thread and mount in the organ bath containg krebs solution at 37⁰ C .Aerate the tissue.
5. Apply 1 gm load and allow the preparation to equilibrate for 30 mins. Using frontal writing lever with 10-12 magnification record the contractions due to increase concentrations of serotonin. Since the muscle contracts slowly and relaxes slowly,a contact time of 90 sec ,and 5 min time cycle.
6. Select two doses form the DRC of standard drug,eliciting sub-maximal responses and bearing a dose ratio 1:2 preferentially and designate them as S1 and S2 and respectively.
7. Select one dose from the DRC of test solution in such a way that the response due to this dose lies preferentially between S1 and S2 and designate it as T.
8. Record 3 sets of responses due to S1 S2 and T adding them to organ bath in a randomized fashion as per Latin square design mentioned in the princilple. The latin square design of addition of doses is followed to ensure good randomization and to account for the fluctuating sensitivity of the tissue.
9. Measure various response to calculate the mean of each response(S1,S2,T)
10. Plot the graph with log dose on X-Axis and % of response on Y –axis and interpolate the T response on to the DRC of standard in between S1 and S2 so as to find the standard dose that gives an equivalent response of that of test.
11. Calculate the potency of the test drug by converting the log of the standard dose that has produced an equivalent response as that of test in to anti-log and report the potency as number of µ gms/ml.
12. Concentration of unknown = $n_1/t \times \text{anti log}\{T-S_1 \times \log n_2/n_1\} C_s$

$$\frac{S_2-S_1}{\text{-----}}$$

Where, n_1 = lower standard dose

(n_2) = Higher standard dose

(t) = test dose

S_1 = response of n_1

S_2 = response of n_2

T = response of t

C_s = Concentration of standard

Report:

The potency of the test drug, serotonin is estimated as ----- $\mu\text{gms/ml}$ by three point method of bioassay.

EX .NO:11

Determination of pA_2 value of prazosin using rat anococcygeus muscle (by Schilds plot method)

Aim: To determine the pA_2 value of prazosin using rat anococcygeus muscle.

Principle:

The pA_2 value is devised by Sir Heinz Otto Schild in Quantitative Pharmacology. In 1947 pA scale, to express drug antagonism.

pA_x value is calculated to compare the potency of antagonists acting on the same receptor.

The pA_x value is defined as the negative logarithm of the molar concentration of the antagonist required to reduce the effect of a multiple dose(x) of the agonist to that of a single dose in the absence of antagonist. The meaning of **pA_2** is the affinity of the antagonist to the receptor. For antagonist, efficacy is 0 and affinity is one.

Higher the pA_x value, more potent is the antagonist. The determination of pA_2 ($X=2$) and pA_{10} ($X=10$) values have wider applications. If the difference between these two values is found to be 0.95 or very near, the antagonism is likely to be of competitive type. An antagonist acting on the same receptor will have same pA_2 value in all the tissue or organ preparations.

Principle of Schild's plot:

- calculation of pA_2 value for an antagonist from the effects observed on isolated smooth muscles can be done in two ways: using Schild's plot procedure or Schild's equation.
- most commonly used method for estimating pA_2 value.
- The Schild plot is a pharmacological method of receptor classification.
- Plot $\log(\text{dose ratio} - 1)$ against negative \log molar concentration of the antagonist (B) used (or directly against B)
- When the slope of the line so obtained is unity, then the antagonism is competitive.

Requirements:

Animal: Rat (150-200 g, overnight fasted)

Drugs : Prazosin stock solution (

EX NO:12

To study the anti-inflammatory property of indomethacin against carrageenan-induced acute paw oedema in rats.

Aim: To study the anti-inflammatory property of indomethacin against carrageenan-induced acute paw oedema in rats.

Principle: Inflammation is a tissue –reaction to infection, irritation or foreign substance. It is a part of the host defence mechanism but when it becomes great it is a hopeless condition. Aging is also considered to be an inflammatory response. There are several tissue factors or mechanisms that are known to be involved in the inflammatory reactions such as release of histamine, bradykinin and prostaglandins.

This method is based upon the ability of anti-inflammatory agents to inhibit the edema produced in the hind paw of the rat after injection of a phlogistic agent (carragennan). The volume of the injected paw is measured before and after the application of irritants. The paw volume of treated animals is compared with control. Plethysmograph is used to measure paw volume.

Requirements:

Animal: Rats, (150-200g)

Equipment: Plethysmograph, (simple apparatus containing mercury. The mercury displacement due to dipping of the paw can be directly read from scale attached to the mercury column or adjusting the mercury level in the arm B to the original level by moving the arm B up/down and note the volume required in both the arms equal)
syringe and needle

Drugs: carrageenan (1% w/v solution and inject 0.1 ml underneath the plantar region)

Indomethacin(Dose 20 mg/kg,s.c,Prepare a stock solution containing 4mg/ml of the drug and inject 0.5 ml/100 g of body weight of the animal).

Saline(0.9%)

Procedure:

1. Weigh the animals and number them.
2. Mark a mark on both the hind paws (right and Left) just beyond tibio-tarsal junction,so that every time the paw is dipped in the mercury column upto the fixed mark to ensure constant paw volume.
3. Note the initial paw volume (both right and left) of each rat by mercury displacement method.
4. Divide the animals into two groups each comprising of atleast four rats. To one group inject saline and to the second group inject indomethacin subcutaneously.
5. After 30 min inject 0.1 ml of 1% (w/v) carragenan in the plantar region of the left paw of control as well as indomethacin –treated group. The right paw will serve as reference non-inflamed paw for comparison.
6. note the paw volume of both legs of control and indomethacin-treated rats at 15,30,60,and 120 min after carragenan challenge.
7. Calculate the percent difference in the right and left paw volumes of each animal of control and indomethacin –treated group. Compare the mean percent change in paw volume in control and drug –treated animals and express as per cent oedema inhibition by the drug.

Report:

EX NO:13

To study the Analgesic effect of morphine in mice using hot plate method.

Aim: To study the Analgesic effect of given drug (morphine) in mice using hotplate method.(Eddy and Leimbach)

Principle: pain is an unpleasant feeling, which make us uncomfortable and reduce the physical as well as mental alertness. Although pain are also useful for us because it acts as a warning signal and it warns about something uncommon inside or outside our body. If the pain is minor it may be tolerated but if the pain becomes severe it has to be managed at earliest.

Analgesia is defined as a state of reduced awareness to pain,and analgesics are substances which decrease pain sensation(pain –killers) by increasing threshold to painful stimuli.The commonly used analgesics are aspirin,paracetamol(non-narcotic type) and morphine (narcotic type).

Painful reaction in experimental animals can be applying noxious (unpleasant)stimuli such as

- (i) Thermal (radiant heat as a source of pain)
- (ii) Chemical (irritants such as acetic acid and bradykinin)
- (iii) Physical pressure(tail compression)

In the laboratory commonly used procedures are tail-flick (tail-withdrawal from the radiant heat)method using analgesiometer,hot plate (jumping from the hot plate at 55 ° C) method and acetic acid –induced writhing.

Requirements:

Animal: Mice (20-25 g)

Equipment: Eddy's hot plate

Drugs: Morphine sulphate (dose 5 mg/kg, sc., prepare a stock solution containing 0.5 mg/ml and inject 1 ml/100 g of body weight of mouse)

Procedure:

1. Weigh and number the mice.
2. Take the basal reaction –time by observing hind paw licking or jump response (whichever appears first) in animals when placed on the hot plate maintained at constant temperature (55° C). normally animals show such response in 6-8 sec. A cut off period of 15 sec is observed to avoid damage to the paws.
3. Inject morphine to animals and note the reaction time of animals on the hot plate at 15, 30, 60 and 120 min after the drug administration. As the reaction time increases with morphine, 15 sec is taken as maximum analgesia and the animals are removed from the hot plate to avoid injury to the paws.
4. Calculate percent increase in reaction time (as index of analgesia) at each time interval.

Observation:**Report:**

EX NO:14

To study the Analgesic effect of morphine in mice using Tail flick method

Aim: To study the Analgesic effect of given drug (morphine) in mice using Tail flick method.

Principle: Pain is an unpleasant feeling, which makes us uncomfortable and reduces the physical as well as mental alertness. Although pain is also useful for us because it acts as a warning signal and it warns about something uncommon inside or outside our body. If the pain is minor it may be tolerated but if the pain becomes severe it has to be managed at the earliest.

Analgesia is defined as a state of reduced awareness to pain, and analgesics are substances which decrease pain sensation (pain-killers) by increasing the threshold to painful stimuli. The commonly used analgesics are aspirin, paracetamol (non-narcotic type) and morphine (narcotic type).

Painful reaction in experimental animals can be by applying noxious (unpleasant) stimuli such as

- (i) Thermal (radiant heat as a source of pain)
- (ii) Chemical (irritants such as acetic acid and bradykinin)
- (iii) Physical pressure (tail compression)

In the laboratory commonly used procedures are tail-flick (tail-withdrawal from the radiant heat) method using analgesiometer, hot plate (jumping from the hot plate at 55 °C) method and acetic acid-induced writhing.

Requirements

Animals: Mice (20-25 g)

Equipment:Analgesiometer

Drugs:Morphine sulphate(dose 5 mg/kg,sc.,prepare a stock solution containing 0.5 mg/ml and inject 1 ml/100 g of body weight of mouse)

Procedure:

1. Weigh and number the mice.
2. Take basal reaction time to radiant heat by placing the tip (last 1-2 cm) of the tail on the radiant heat source.The tail-withdrawal from the heat (flicking response) is taken as the end point.Normallu a mouse withdraws its tail within 3-5 sec.A cut off period of 10-12 sec is observed to prevent damage to the tail.Any animal failing to withdraw its tail in 3-5 sec is rejected from the study.Take at least 3-5 basal reaction times for each mouse at a gap of 5min to confirm normal behaviour of the animal.
3. Inject morphine and note the reaction time at 5,15,30,60 min after the drug.As the reaction time reaches 10 sec it is considered maximum analgesia and the tail is removed from the source of heat to avoid tissue damage.
4. Calculate percentage increase in reaction time (index of analgesia)at each time interval.

Observation:

Report:

EX NO:15

To study the Analgesic effect of morphine against acid-inducing writhing in mice

Aim:To study the Analgesic effect of morphine against acid-inducing writhing in mice.

Principle:Painful reactions in animals may be produced by chemicals also.Intraperitoneal injection of phenylquinone,bradykinin or acetic acid produces pain reaction which is characterised as a writhing response.Constriction of abdomen,turning of trunk (twist) and extension of hind legs are taken as reaction to chemically induced pain.Analgesics,both narcotic and non-narcotic type,inhibit writhing response.

Requirements

Animals:Mice (25-30 g)

Drugs: Morphine sulphate (dose 5 mg/kg,sc.,prepare a stock solution containing 0.5 mg/ml and inject 1 ml/100 g of body weight of mouse),acetic acid 1%v/v Inject 1 ml/100 g of body weight of the animal.

Procedure:

1. Weigh and number the mice.
2. Divide the animals into two groups, each consisting of 5 animals.Administer appropriate volume of acetic acid solution to the first group(which serves as control), place them individually under glass jar for observation.
3. Note the onset on wriths,.Record the number of abdominal contractions,trunk twist response and extension of hind limbs as well as the number of animals showing such response during a period of 10 min.
4. To the second group of animals inject morphine. Fifteen minutes later, administer acetic acid solution to these animals. Note the onset and severity of writhing response as done in step 3.

5. Calculate the mean writhing scores in control and morphine treated groups. Note the inhibition of pain response by morphine.

Berhampur, Odisha**

5. Pharmacology of drugs acting on endocrine system

A. ANDROGENS AND ANABOLIC STEROIDS

Androgens (Male Sex Hormones):

- Testosterone is the main natural androgen. It is synthesised mainly by the interstitial cells of the testis, and in smaller amounts by the ovaries and adrenal cortex.
- These are substances which cause development of secondary sex characters in the castrated male. That testes are responsible for the male characters is known since prehistoric times.
- Its endocrine function was established by Berthold in 1849. Testosterone was isolated, its structure worked out and synthesized by the year 1935.
- Androgens are may be natural and synthetic.

Natural androgens:

- Testes of adult male produce 5-12 mg of testosterone daily, a part of which is converted in extraglandular tissues to the more active dihydrotestosterone; by the enzyme steroid 5 α -reductase; cholesterol is the starting material.
- Adrenal cortex produces small quantities of dehydroepiandrosterone and androstenedione which are called 'weak androgens' (potency 1/20 to 1 /30), but are infact inactive as such and derive their weak activity from partial conversion to testosterone by peripheral tissues. Adrenals themselves do not produce significant quantity of testosterone.
- In women ovary produces small quantity of testosterone; this together with that derived indirectly from adrenals amounts to 0.25-0.5 mg/ day.
- Androsterone is a metabolite of testosterone which is excreted in urine. It has 1 /10 the activity of testosterone.

Synthetic androgens:

- **Methyltestosterone** and **fluoxymesterone** are 17-alkyl substituted derivatives of testosterone which are orally active because of resistance to first pass metabolism, but have submaximalandrogenic efficacy and potential to cause cholestatic jaundice.
- Other orally active compounds are **testosterone undecanoate** which administered as oily solution is absorbed through lymphatics bypassing the liver and **mesterolone**.
- A number of lipidsoluble esters of testosterone have been produced, suitable for injection in oily vehicle, from which they are absorbed slowly and exert prolonged action afterdeesterification in the body.

Regulation of secretion

- Testosterone is secreted by the interstitial (Leydig) cells of the testes under the influence of pulsatile secretion of LH from pituitary.
- FSH is mainly responsible for promotion of spermatogenesis in tubular (Sertoli) cells.
- While relatively high concentration of testosterone inhibits LH secretion and in time causes atrophy of interstitial cells, it has only weak inhibitory action on FSH secretion.
- Estrogens are more potent inhibitors of Gn secretion even in males and it is believed that the small amount of estradiol produced by testes and that resulting from conversion of testosterone to estradiol plays a role in feedback inhibition.
- Inhibin, (a protein) produced by Sertoli cells, has strong FSH inhibitory action and may be mediating the feedback inhibition.
- Testosterone and estradiol act on hypothalamus to reduce GnRH as well as act directly on pituitary.
- The plasma level of testosterone in adult males ranges from 0.3 to 1 pg/ dl and in females from 20 to 60 ng/ dl.

Fig.1: Regulation and production of sex steroids in the male

Actions:**1. Sex organs and secondary sex characters(Androgenic)**

Testosterone is responsible for all the changes that occur in a boy at puberty:

- Growth of genitals-penis, scrotum, seminal vesicles, prostate.
- Growth of hair-pubic, axillary, beard, moustache, body hair and male pattern of its distribution.

- Thickening of skin which becomes greasy due to proliferation and increased activity of sebaceous glands.
- Subcutaneous fat is lost and veins look prominent.
- Larynx grows and voice deepens.
- Behavioral effects are increased physical vigour, aggressiveness, penile erections. Male libido appears to be activated by testosterone directly as well as by estradiol produced from testosterone.
- Testosterone is also important for the intrauterine development of the male phenotype; relatively large amounts are produced by the foetal testes during the first half of intrauterine life.

2. Testes:

- Moderately large doses cause testicular atrophy by inhibiting Gn secretion from pituitary. Still larger doses have a direct sustaining effect and atrophy is less marked. Testosterone is needed for normal spermatogenesis and maturation of spermatozoa. High concentration of testosterone attained locally in the spermatogenic tubules by diffusion from the neighbouring Leydig cells stimulates spermatogenesis.

3. Skeleton and skeletal muscles (Anabolic):

- Testosterone is responsible for the pubertal spurt of growth in boys and to a smaller extent in girls.
- There is rapid bone growth, both in thickness as well as in length. After puberty, the epiphyses fuse and linear growth comes to a halt. There is evidence now that estradiol produced from testosterone, and not testosterone itself, is responsible for fusion of epiphyses in boys as well as girls. Moreover, estradiol appears to supplement the effect of testosterone on bone mineralization.
- Testosterone also promotes muscle building, especially if aided by exercise. There is accretion of nitrogen, minerals (Na, K, Ca, P, S) and water-body weight increases rapidly, more protoplasm is built.
- Appetite is improved and a sense of well-being prevails.

4. Erythropoiesis

- Testosterone also accelerates erythropoiesis by increasing erythropoietin production and probably direct action on haem synthesis.

Mechanism of action

- In most target cells, testosterone works through an active metabolite, dihydrotestosterone, to which it is converted locally by a 5 α -reductase enzyme.

- In contrast, testosterone itself causes virilisation of the genital tract in the male embryo and regulates LH/ICSH production in anterior pituitary cells.
- Testosterone and dihydrotestosterone modify gene transcription by interacting with cytoplasmic receptors. The effects are expressed through modification of protein synthesis.

Preparations:

- Testosterone itself can be given by subcutaneous implantation or by transdermal patches.
- Various esters (e.g. enanthate and propionate) are given by intramuscular depot injection.
- Testosterone undecanoate and mesterolone can be given orally.

Pharmacokinetic:

- If given orally, testosterone is rapidly metabolised in the liver. It is therefore usually injected.
- Virtually all testosterone in the circulation is bound to plasma protein-mainly to the sex steroid-binding globulin.
- The elimination half-life of free testosterone is short (10-20 minutes). It is inactivated in the liver by conversion to androstenedione.
- This has weak androgenic activity in its own right and can be reconverted to testosterone, although approximately 90% of testosterone is eliminated as metabolites rather than the parent compound.
- Synthetic androgens are less rapidly metabolised, and some are excreted in the urine unchanged.

Unwanted effects:

- Unwanted effects of androgens include eventual decrease of gonadotrophin release, with resultant infertility, and salt and water retention leading to oedema.
- Adenocarcinoma of the liver has been reported. Androgens impair growth in children (via premature fusion of epiphyses), cause acne, and lead to masculinisation in girls.
- Adverse effects of testosterone replacement and monitoring for these are reviewed by Rhoden & Morgentaler (2004).
- Gynaecomastia: may occur, especially in children and in patients with liver disease. This is due to peripheral conversion of testosterone to estrogens.

Contraindications:

- Androgens are contraindicated in carcinoma of prostate and male breast, liver and kidney disease and during pregnancy (masculinization of female foetus).
- They should be used cautiously in patients who may be adversely affected by fluid retention-such as CHF, epilepsy, migraine.

Clinical use:

Androgens (testosterone preparations) as hormone replacement in:

- male hypogonadism due to pituitary or testicular disease (e.g. 2.5 mg/day patches)
- hyposexuality following ovariectomy (e.g. 300µg/day patches).
- Testosterone therapy has been shown to improve weakness and muscle wasting in AIDS patients with low testosterone levels.
- Because testosterone levels decline in old age, it has been administered to elderly males and found to improve bone mineralization and muscle mass.

Anabolic Steroids:

- These are synthetic androgens with supposedly higher anabolic and lower androgenic activity. Androgens can be modified chemically to alter the balance of anabolic and other effects.
- The anabolic : androgenic ratio of testosterone is considered as 1; The anabolic selectivity of these steroids is modest with ratios between 1 to 3 in the rat model, and probably still lower in man.
- Drugs as anabolic steroids are Nandrolone, Oxymetholone, Stanozolol and Methandienone.
- The anabolic effects are similar to that of testosterone and are mediated through the same receptor as the androgenic effects.
- Such 'anabolic steroids' (e.g. nandrolone) increase protein synthesis and muscle development, but clinical use (e.g. in debilitating disease) has been disappointing.
- They may be used in catabolic states like: acute illness, severe trauma, major surgery, etc. are associated with negative N balance. They are used in the therapy of aplastic anaemia, Osteoporosis, Suboptimal growth in boys, Renal insufficiency and (notoriously) abused by some athletes.
- Unwanted effects are described above, under Androgens. In addition, cholestatic jaundice, liver tumours and increased risk of coronary heart disease are recognised adverse effects of high-dose anabolic steroids.

Antiandrogens:

- Both oestrogens and progestogens have antiandrogen activity, oestrogens mainly by inhibiting gonadotrophin secretion and progestogens by competing with androgens in target organs.
- Cyproterone is a derivative of progesterone and has weak progestational activity. It is a partial agonist at androgen receptors, competing with dihydrotestosterone for receptors in androgen-sensitive target tissues. Through its effect in the hypothalamus, it depresses the synthesis of gonadotrophins. It is used as an adjunct in the treatment of prostatic cancer during initiation of GnRH treatment. It is also used in the therapy of precocious puberty in males, and of masculinisation and acne in women. It also has a central nervous system effect, decreasing libido, and has been used to treat hypersexuality in male sexual offenders.
- Danazol is an orally active ethisterone derivative having weak androgenic, anabolic and progestational activities. Though labelled as an impeded/ attenuated androgen, because it binds to the androgen receptor and induces some androgen-specific mRNA production, the most prominent action is suppression of Gn secretion from pituitary in both men and women leads to inhibition of testicular / ovarian function. It suppresses gonadal function directly as well by inhibiting steroidogenic enzymes.
- Flutamide is a non-steroidal antiandrogen used with GnRH in the treatment of prostate cancer. It is having specific antiandrogenic, but no other hormonal activity. Its active metabolite 2-hydroxyflutamide competitively blocks androgen action on accessory sex organs as well as on pituitary-increases LH secretion by blocking feedback inhibition. Bicalutamide is more potent and longer acting congener of flutamide and is suitable for once daily administration in metastatic carcinoma of prostate.
- Drugs can have antiandrogen action by inhibiting synthetic enzymes. Finasteride inhibits the enzyme (5 α -reductase) that converts testosterone to dihydrotestosterone, which has greater affinity than testosterone for androgen receptors in the prostate gland. Finasteride is well absorbed after oral administration, has a half-life of about 7 hours, and is excreted in the urine and faeces. It is used to treat benign prostatic hyperplasia.
- Dutasteride is the newer congener of Finasteride inhibits both type 1 and type 2 5 α -reductase and reduces dihydrotestosterone level.

Clinical uses of antiandrogens

- Antiandrogens (e.g. flutamide, cyproterone) are used as part of the treatment of prostatic cancer. 5α -Reductase inhibitors (e.g. finasteride) are used in benign prostatic hypertrophy.

B. ESTROGENS, PROGESTERONE AND ORAL CONTRACEPTIVES:

At puberty, an increased output of the hormones of the hypothalamus and anterior pituitary stimulates secretion of oestrogenic sex steroids. These are responsible for the maturation of the reproductive organs and the development of the secondary sexual characteristics, and also for a phase of accelerated growth followed by closure of the epiphyses of the long bones. Sex steroids are thereafter involved in the regulation of the cyclic changes expressed in the menstrual cycle, and are important in pregnancy. A simplified outline of the inter-relationship of these substances in the physiological control of the menstrual cycle is given in the following figures.

Fig. 2: Hormonal control of the female reproductive system.

The Graafian follicle (GF) is shown developing on the left, then involuting to form the corpus luteum (CL) on the right, after the ovum (•) has been released. FSH, follicle-stimulating hormone; GnRH, gonadotrophin-releasing hormone; LH, luteinising hormone.

Hormonal control of the female reproductive system

- The menstrual cycle starts with menstruation.

- Gonadotrophin-releasing hormone, released from the hypothalamus, acts on the anterior pituitary to release follicle-stimulating hormone (FSH) and luteinising hormone (LH).
- FSH and LH stimulate follicle development in the ovary. FSH is the main hormone stimulating oestrogen release. LH stimulates ovulation at mid-cycle and is the main hormone controlling subsequent progesterone secretion from the corpus luteum.
- Oestrogen controls the proliferative phase of the endometrium and has negative feedback effects on the anterior pituitary. Progesterone controls the later secretory phase, and has negative feedback effects on both hypothalamus and anterior pituitary.
- If a fertilised ovum is implanted, the corpus luteum continues to secrete progesterone.
- After implantation, human chorionic gonadotrophin from the chorion becomes important, and later in pregnancy progesterone and other hormones are secreted by the placenta.

Estrogens (Oestrogens):

- Estrogens are synthesised by the ovary and placenta, and in small amounts by the testis and adrenal cortex.
- As for other steroids, the starting substance for oestrogen synthesis is cholesterol.
- The immediate precursors to the estrogens are androgenic substances-androstenedione or testosterone.
- These are substances which can induce estrus in spayed animals.

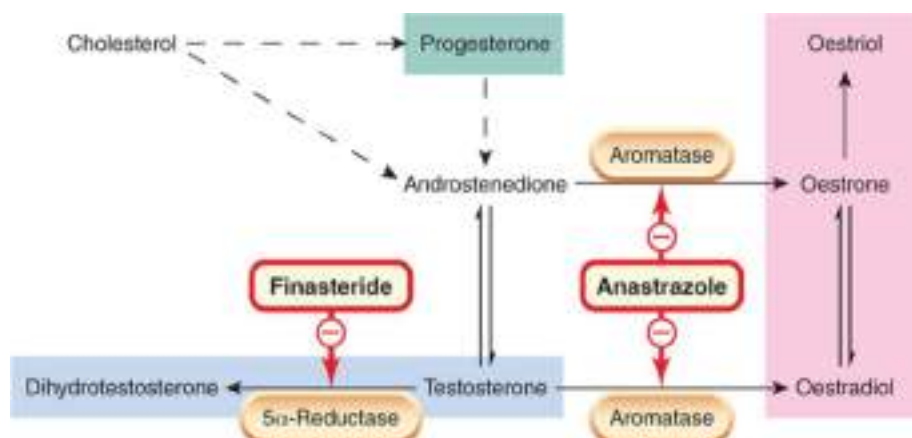

Fig. 3: The biosynthetic pathway for the oestrogens, with sites of drug action

Natural estrogens:

- There are three main endogenous estrogens in humans: estradiol, estrone and estrinol. Estradiol is the most potent and is the principal estrogen secreted by the ovary.
- It is synthesized in the graafian follicle, corpus luteum and placenta from cholesterol.

- Estradiol is rapidly oxidized in liver to estrone which is hydroxylated to form estriol.
- All three are found in blood, but estradiol is the most potent estrogen.
- At the beginning of the menstrual cycle, the plasma concentration is 0.2 nmol/l, rising to ~2.2 nmol/l in mid-cycle.
- Small quantity (2-20 pg/ day) of estradiol is derived in human males also from aromatization of testosterone in the testes and extraglandular tissues.
- In mare, large quantity of equilin is produced which has 1/5 estrogenic potency of estradiol.

Fig. 4: Structure of natural and synthetic estrogens

Synthetic estrogens:

- Natural estrogens are inactive orally and have a short duration of action due to rapid metabolism in liver.
- To overcome this, synthetic compounds have been produced:
 - Steroidal: Ethinylestradiol, Mestranol, Tibolone.
 - Nonsteroidal: Diethylstilbestrol (stilbestrol) Hexestrol, Dienestrol

Regulation of secretion:

- The daily secretion of estrogens in menstruating women varies from 10-100 µg depending on the phase of the cycle.
- Secretion starts from the graafian follicle under the influence of FSH and the blood level rises gradually during the follicular phase.
- Due to the modest preovulatory FSH surge, estrogens further rise transiently.
- After ovulation, corpus luteum continues to secrete estrogens till about two days before menstruation.
- Estrogens exercise feedback inhibition of FSH (also LH at higher concentrations) by direct action on pituitary as well as through hypothalamus.
- During pregnancy, placenta secretes large quantities of estrogens, reaching a peak of up to 30 mg/ day at term.
- Their level declines sharply after delivery.

- In the postmenopausal women, daily production of estrogen has been estimated as 2-10 µg-derived primarily by extra glandular aromatization of adrenal androgens.

Actions:**1) Sex organs:**

- The estrogens bring about pubertal changes in the female including growth of uterus, fallopian tubes and vagina. Vaginal epithelium gets thickened, stratified and cornified.
- They are responsible for the proliferation of endometrium in the preovulatory phase and it is only in concert with estrogens that progesterone brings about secretory changes.
- Oestrogen acts in concert with progesterone, and induces synthesis of progesterone receptors in uterus, vagina, anterior pituitary and hypothalamus.
- Conversely, progesterone decreases oestrogen receptor expression in the reproductive tract.
- Prolactin also influences oestrogen action by increasing the numbers of oestrogen receptors in the mammary gland, but has no effect on oestrogen receptor expression in the uterus.

2) Secondary sex characters

- Estrogens produced at puberty cause growth of breasts-proliferation of ducts and stroma, accumulation of fat.
- The pubic and axillary hair appear, feminine body contours and behaviour are influenced.

3) Metabolic effects:

- Estrogens are anabolic similar to but weaker than testosterone. Therefore, small amount of androgen may be contributing to the pubertal growth spurt even in females.
- Oestrogens have several metabolic actions, including mineralocorticoid (retention of salt and water) and mild anabolic actions.
- They increase plasma concentrations of high-density lipoproteins, a potentially beneficial effect that may contribute to the relatively low risk of atheromatous disease in premenopausal women compared with men of the same age.
- Oestrogens increase the coagulability of blood, and increase the risk of thromboembolism. This effect is dose-related.

Effects of exogenous oestrogen

- depend on the state of sexual maturity when the oestrogen is administered:
 - in primary hypogonadism: oestrogen stimulates development of secondary sexual characteristics and accelerates growth
 - in adults with primary amenorrhoea: oestrogen, given cyclically with a progestogen, induces an artificial cycle
 - in sexually mature women: oestrogen (with a progestogen) is contraceptive
 - at or after the menopause: oestrogen replacement prevents menopausal symptoms and bone loss.

Mechanism of action:

- As with other steroids, oestrogen binds to specific nuclear receptors in target cells and produce effects by regulating protein synthesis.
- Estrogen receptors (ERs) have been demonstrated in female sex organs, breast, pituitary, liver, bone, blood vessels, heart, CNS and in certain hormone responsive breastcarcinoma cells.
- There are two types of ER, termed ER α ; and ER β , have been identified, cloned and structurally characterized. Most tissues express both subtypes but ER α predominates in uterus, vagina, breast, hypothalamus and blood vessels, while ER β predominates in prostate gland of males and ovaries in females.
- Binding is followed by interaction of the resultant complexes with nuclear sites and subsequent genomic effects-either gene transcription (i.e. DNA-directed RNA and protein synthesis) or gene repression (inhibition of transcription).
- Estradiol binds to both ER α and ER β with equal affinity, but certain ligands may have differing affinities.

Preparations

- Many preparations (oral, transdermal, intramuscular, implantable and topical) of oestrogens are available for a wide range of indications.
- These preparations include natural (e.g. estradiol, estriol) and synthetic (e.g. mestranol, ethinylestradiol, stilbestrol) estrogens.
- Estrogens are presented either as single agents or combined with progestogen.

Pharmacokinetic

- Natural as well as synthetic oestrogens are well absorbed in the gastrointestinal tract, but after absorption the natural oestrogens are rapidly metabolised in the liver, whereas synthetic oestrogens are degraded less rapidly.
- Estradiol esters injected i.m. are slowly absorbed and exert prolonged action.

- There is a variable amount of enterohepatic cycling, which forms the basis for drug interaction, because broad-spectrum antibiotic use alters bowel flora and can thereby render oral contraception ineffective.
- Most estrogens are readily absorbed from skin and mucous membranes. They may be given topically in the vagina as creams or pessaries for local effect.
- In the plasma, natural oestrogens are bound to albumin and to a sex steroid-binding globulin.
- Natural oestrogens are excreted in the urine as glucuronides and sulfates.

Clinical use:

- Hormone replacement therapy:
 - primary ovarian failure (e.g. Turner's syndrome)
 - secondary ovarian failure (menopause) for flushing, vaginal dryness and to preserve bone mass.
- Contraception
- Prostate and breast cancer

Unwanted effects

- Unwanted effects of oestrogens include tenderness in the breasts, nausea, vomiting, anorexia, retention of salt and water with resultant oedema, and increased risk of thromboembolism.
- Used intermittently for postmenopausal replacement therapy, oestrogens cause menstruation-like bleeding. Oestrogen causes endometrial hyperplasia unless given cyclically with a progestogen. When administered to males, oestrogens result in feminisation.
- Oestrogen administration to pregnant women can cause genital abnormalities in their offspring. Carcinoma of the vagina was more common in young women whose mothers were given stilbestrol in early pregnancy in a misguided attempt to prevent miscarriage

Antiestrogens and Selective Estrogen Receptor Modulators (SERMs)**Antiestrogens:**

- Antioestrogens compete with natural oestrogens for receptors in target organs.
- Two nonsteroidal compounds **clomiphencitrate** and **tamoxifencitrate** previously grouped as estrogen antagonists have been in use since 1970s.
- **Clomiphene** inhibits oestrogen binding in the anterior pituitary, so preventing the normal modulation by negative feedback and causing increased secretion of GnRH

and gonadotrophins. This results in a marked stimulation and enlargement of the ovaries and increased oestrogen secretion. The main effect of their antioestrogen action in the pituitary is that they induce ovulation. It is used in treating infertility caused by lack of ovulation. Twins are common, but multiple pregnancy is unusual.

SERMs:

- The recent discovery of two estrogen receptors (ERs) and that ligand binding could change their configuration in multiple ways allowing interaction with different coactivators and corepressors in a tissue specific manner has paved the way for development of compounds with unique profile of agonistic and antagonistic actions in different tissues.
- These drugs have been designated 'selective estrogen receptor modulators' and two new compounds Raloxifene and Ormeloxifene have been marketed. It has been demonstrated that the conformation of ER after binding tamoxifen or raloxifene is different from that after binding estradiol.
- **Tamoxifen** has antioestrogenic action on mammary tissue but oestrogenic actions on plasma lipids, endometrium and bone. It produces mild oestrogen-like adverse effects consistent with partial agonist activity. The tamoxifen-oestrogen receptor complex does not readily dissociate, so there is interference with the recycling of receptors. Tamoxifen up-regulates transforming growth factor- β , decreased function of which is associated with the progression of malignancy, and which has a role in controlling the balance between bone-producing osteoblasts and bone-resorbing osteoclasts. Side effects are hot flushes, vomiting, vaginal bleeding, vaginal discharge, menstrual irregularities, increased risk of venous thromboembolism, dermatitis, anorexia, depression and mild leucopenia. It is much less toxic than other anticancer drugs.
- **Raloxifene**, a 'selective oestrogen receptor modulator', has antiestrogenic effects on breast and uterus but estrogenic effects on bone, lipid metabolism and blood coagulation. It is used for prevention and treatment of postmenopausal osteoporosis and reduces the incidence of estrogen receptor-positive breast cancer, although its role in therapy of breast cancer is undefined. Unlike estrogen, it does not prevent menopausal flushes. Side effects are hot flushes, leg cramps are generally mild; vaginal bleeding is occasional. The only serious concern is 3-fold increase in risk of deep vein thrombosis and pulmonary embolism. However, similar risk attends estrogen HRT.

- **Ormeloxifene** a distinct new SERM which acts as estrogen antagonist in breast and uterus. It suppresses endometrial proliferation by regulating their ER. Excessive uterine bleeding with anovular cycles occurring near menopause is normalized. However, vaginal epithelium and cervical mucus are not altered. It may have contraceptive property. Ormeloxifene is approved for treatment of dysfunctional uterine bleeding. Side effects are nausea, headache, fluid retention, weight gain, rise in BP and prolongation of menstrual cycles.

Clinical use of antiestrogens

- To treat oestrogen-sensitive breast cancer (tamoxifen).
- To induce ovulation (clomiphene) in treating infertility.

Progesterone:

- The natural progestational hormone (progestogen) is progesterone. This is secreted by the corpus luteum in the second part of the menstrual cycle, and by the placenta during pregnancy. Small amounts are also secreted by testis and adrenal cortex.
- These are substances which convert the estrogen primed endometrium to secretory and maintain pregnancy in animals spayed after conception (Progestin = favouring pregnancy).

Natural progestin:

- Progesterone, a 21 carbon steroid, is the natural progestin and is derived from cholesterol.
- It is secreted by the corpus luteum (10-20 mg; day) in the later half of menstrual cycle under the influence of LH.
- Its production declines a few days before the next menstrual flow.
- If the ovum gets fertilized and implants the blastocytes immediately starts producing chorionic gonadotropin which is absorbed and sustains the corpus luteum in early pregnancy.
- Placenta starts secreting lots of estrogens and progesterone from 2nd trimester till term. Men produce 1-5 mg progesterone per day from adrenals and testis, its role if any, in males is not known.

Synthetic progestins:

- A number of synthetic progestins with high oral activity have been produced.
- These are either progesterone derivatives (21 C) or 19-nortestosterone derivatives also called estranes (18 C).

- The progesterone derivatives are almost pure progestins, have weaker anti-ovulatory action and are used primarily as adjuvants to estrogens for HRT.

Progesterone derivatives:

- Medroxyprogesterone acetate, Megestrol acetate, Dydrogesterone, Hydroxyprogesterone caproate and Newer compound- Norgestrel acetate.
- **19- Nortestosterone derivatives:**
 - **Older compounds:** Norethindrone (Norethisterone), Lynestrenol (Ethinylestrenol), Allylestrenol, Levonorgestrel (Gonane).
 - **Newer compounds:** (Gonanes) Desogestrel, Norgestimate, Gestodene

Actions:

- The main function of progesterone is preparation of the uterus for nidation and maintenance of pregnancy. The latter is due to prevention of endometrial shedding, decreased uterine motility and inhibition of immunological rejection of the foetus: progesterone depresses T-cell function and cell-mediated immunity (CMI).

1. Uterus:

- Progesterone brings about secretory changes in the estrogen primed endometrium: hyperemia, tortuosity of glands and increased secretion occurs while epithelial proliferation is suppressed.
- It is lack of progestational support which causes mucosal shedding during menstruation.

2. Cervix:

- Progesterone converts the watery cervical secretion induced by estrogens to viscid, scanty and cellular secretion which is hostile to sperm penetration.

3. Vagina:

- Progesterone induces pregnancy like changes in the vaginal mucosa- leukocyte infiltration of cornified epithelium.

4. Breast:

- Progesterone causes proliferation of acini in the mammary glands.
- Cyclic epithelial proliferation occurs during luteal phase, but continuous exposure to progesterone during pregnancy halts mitotic activity and stabilizes mammary cells.
- Acting in concert with estrogens, it prepares breast for lactation. Withdrawal of these hormones after delivery causes release of prolactin from pituitary and milk secretion starts.

5. CNS:

- High circulating concentration of progesterone (during pregnancy) appears to have a sedative effect.

6. Body temperature:

- It causes a slight (0.5°C) rise in body temperature by resetting the hypothalamic thermostat and increasing heat production. This is responsible for the higher body temperature seen during the luteal phase.

7. Respiration:

- Progestins in relatively higher doses stimulate respiration, as occurs during pregnancy.

8. Metabolism:

- Prolonged use of oral contraceptives impairs glucose tolerance in some women. This has been ascribed to the progestational component.
- Progestins, especially those with androgenic activity (19-nortestosterone derivatives) tend to raise LDL and lower HDL levels.
- This may reduce the beneficial effect of estrogen used concurrently in HRT or in contraceptives.
- Micronized oral progesterone formulation (referred to as 'natural progesterone' introduced recently has been shown not to counteract the beneficial effect of estrogen on LDL and HDL.

9. Pituitary:

- Progesterone is a weak inhibitor of Gn secretion from pituitary. It decreases the frequency of LH pulses by action on hypothalamic pulse generator but increases the amount of LH secreted per pulse.
- Administration of progestin during follicular phase suppresses the preovulatory LH surge and prevents ovulation; synergises with estrogen for this action.

Mechanism of action:

- Unlike other steroid receptors, the progesterone receptor (PR) has a limited distribution in the body: confined mostly to the female genital tract, breast, CNS and pituitary. The PR is normally present in the nucleus of target cells.
- Analogous to ER, upon binding the hormone PR undergoes dimerization, attaches to progesterone response element (PRE) of target genes and regulates transcription through coactivators. The anti-progestins also bind to PR, but the conformation assumed is different from agonist bound receptor and opposite effects are produced by interaction with corepressors.

Pharmacokinetic:

- Injected progesterone is bound to albumin, not to the sex steroid-binding globulin. Some is stored in adipose tissue. It is metabolised in the liver, and the products, pregnanolone and pregnanediol, are conjugated with glucuronic acid and excreted in the urine.

Unwanted effects:

- Unwanted effects of progestogens include weak androgenic actions. Other unwanted effects include acne, fluid retention, weight change, depression, change in libido, breast discomfort, premenstrual symptoms, irregular menstrual cycles and breakthrough bleeding. There is an increased incidence of thromboembolism.

Clinical use of progestogens:

- Contraception:
 - with oestrogen in combined oral contraceptive pill
 - as progesterone-only contraceptive pill
 - as injectable or implantable progesterone-only contraception
 - as part of an intrauterine contraceptive system.
- Combined with oestrogen for oestrogen replacement therapy in women with an intact uterus, to prevent endometrial hyperplasia and carcinoma.
- For endometriosis.
- In endometrial carcinoma; use in breast and renal cancer has declined.
- Poorly validated uses have included various menstrual disorders.

Antiprogestogens:**Mifepristone:**

- Mifepristone is a 19-norsteroid with potent competitive antiprogestational and significant antiglucocorticoid as well as antiandrogenic activity.
- It is a partial agonist and competitive antagonist. It sensitises the uterus to the action of prostaglandins.
- Given during the follicular phase, its anti progestin action results in attenuation of midcycle Gn surge from pituitary and slowing of follicular development and delay/failure of ovulation.

- During the luteal phase, it prevents secretory changes normally brought about by progesterone. Later in the cycle, it blocks progesterone support to the endometrium, unrestrains PG release from it and this stimulates uterine contractions.
- It is given orally and has a plasma half-life of 21 hours.

Clinical use of antiprogestogens

- Mifepristone is used, in combination with a prostaglandin, as a medical alternative to surgical termination of pregnancy.
- Surgical ripening: 24-30 hours before attempting surgical abortion or induction of labour, Mifepristone 600 mg results in softening of cervix.
- Postcoital contraceptive: Mifepristone 600 mg given within 72 hr of intercourse.
- Once-a-month contraceptive: A single 200 mg of mifepristone given 2 days after mid-cycle each month prevents conception on most of the occasion.

Oral Contraceptives:**Female Contraception:**

- Over 100 million women worldwide are currently using hormonal contraceptives.
- With these drugs, fertility can be suppressed at will, for as long as desired, with almost 100% confidence and complete return of fertility on discontinuation. The efficacy, convenience, low cost and overall safety of oral contraceptives (OCs) has allowed women to decide if and when they will become pregnant and to plan their activities.
- A variety of oral and parenteral preparations are now available offering individual choices.

Oral Contraceptives:

- There are two main types of oral contraceptives:
 - combinations of an oestrogen with a progestogen (the combined pill)
 - progestogen alone (the progestogen-only pill).

1. Combined pill:

- It contains an estrogen and a progestin. With accumulated experience, it has been possible to reduce the amount of estrogen and progestin in the 'second generation' OC pills without compromising efficacy, but reducing side effects and complications. 'Third generation' pills containing newer progestins like desogestrel with improved profile of action have been introduced in the 1990s.

- Ethinylestradiol 30 µg daily is considered threshold but can be reduced to 20µg/ day if a progestin with potent antioviulatory action is included.
- The progestin is a 19- nortestosterone because these have potent antioviulatory action.
- Used alone the ovulation inhibitory dose (per day) of the currently used progestins is estimated to be- levonorgestrel 60 µg, desogestrel 60 µg, norgestirdate 200 µg, gestodene 40 µg, but the amount in the pill is 2-3 times higher to attain 100% certainty.
- While both estrogens and progestins synergise to inhibit ovulation, the progestin ensures prompt bleeding at the end of a cycle and blocks the risk of developing endometrial carcinoma due to the estrogen.
- One tablet is taken daily for 21 days, starting on the 5th day of menstruation. The next course is started after a gap of 7 days in which bleeding occurs. Thus, a cycle of 28 days is maintained. Calendar packs of pills are available.
- This is the most popular and most efficacious method.
- The mode of action of combined oral contraceptive pill is as follows:
 - oestrogen inhibits secretion of FSH via negative feedback on the anterior pituitary, and thus suppresses development of the ovarian follicle.
 - progestogen inhibits secretion of LH and thus prevents ovulation; it also makes the cervical mucus less suitable for the passage of sperm.
 - oestrogen and progestogen act in concert to alter the endometrium in such a way as to discourage implantation.

2. Phased regimens:

- These have been introduced to permit reduction in total steroid dose without compromising efficacy. These are biphasic or triphasic.
- The estrogen dose is kept constant (or varied slightly between 30-40 µg), while the amount of progestin is low in the first phase and progressively higher in the second and third phases.
- Phasic pills are particularly recommended for women over 35 years of age or when other risk factors are present.

3. Minipill (progestin only pill):

- It has been devised to eliminate the estrogen, because many of the long-term risks have been ascribed to this component.

- A low-dose progestin only pill is taken daily continuously without any gap. The menstrual cycle tends to become irregular and ovulation occurs in 20-30% women, but other mechanisms contribute to the contraceptive action.
- The efficacy is lower (96-98%) compared to 98-99.9% with combined pill. Look for pregnancy if amenorrhoea of more than 2 months occurs. This method is less popular.

4. Postcoital (emergency) contraception:

Currently 3 regimens are used in a woman not taking any contraceptive who had a sexual intercourse risking unwanted pregnancy.

- Levonorgestrel 0.75 mg two doses 12 hours apart or 1.5 mg single dose taken as soon as possible, but before 72 hours of unprotected intercourse. Levonorgestrel 0.75 mg + ethinylestradiol 0.1 mg (Yuzpe method) 2 doses at 12 hour interval within 72 hours of exposure was used earlier.
- Ulipristal 30 mg single dose as soon as possible, but within 120 hours of unprotected intercourse.
- Mifepristone 600 mg single dose taken within 72 hours of intercourse has been used.

Common adverse effects:

- The common effects are: weight gain, owing to fluid retention or an anabolic effect, or both mild nausea, flushing, dizziness, depression or irritability skin changes (e.g. acne and/or an increase in pigmentation) amenorrhoea of variable duration on cessation of taking the pill.

C. DRUGS ACTING ON THE UTERUS:

Motility of the uterus:

Uterine muscle contracts rhythmically both in vitro and in vivo, the contractions originating in the muscle itself. Myometrial cells in the fundus act as pacemakers and give rise to conducted action potentials. The electrophysiological activity of these pacemaker cells is regulated by the sex hormones.

The non-pregnant human uterus contracts spontaneously but weakly during the first part of the cycle, and more strongly during the luteal phase and during menstruation. Uterine movements are depressed in early pregnancy because oestrogen, potentiated by progesterone, hyperpolarises myometrial cells. This suppresses spontaneous contractions. Towards the end of gestation, however, contractions recommence; these increase in force and frequency, and become fully coordinated during parturition. The nerve supply to the uterus includes both excitatory and inhibitory sympathetic components: adrenaline, acting on β_2 -adrenoceptors,

inhibits uterine contraction, whereas noradrenaline, acting on α -adrenoceptors, stimulates contraction.

Uterine Stimulants (Oxytocics, Abortifacients):

These drugs increase uterine motility, especially at term.

- 1. Posterior pituitary hormone:** Oxytocin, Desamino oxytocin
- 2. Ergot alkaloids:** Ergometrine (Ergonovine), Methylergometrine
- 3. Prostaglandins:** PGE₂, PGF_{2 α} , 15-methylPGF_{2 α} , Misoprostol

Oxytocin:

- Oxytocin is a nonapeptide secreted by the posterior pituitary along with vasopressin (ADH). Both oxytocin and ADH are synthesized within the nerve cell bodies in supraoptic and paraventricular nuclei of hypothalamus; are transported down the axon and stored in the nerve endings within the neurohypophysis. They are stored in separate neurones as complexes with their specific binding proteins (neurophysins).
- Oxytocin released by stimuli by -coitus, parturition, suckling.

Actions:

- **Uterus:** Oxytocin contracts the uterus. Oestrogen induces oxytocin receptor synthesis and, consequently, the uterus at term is highly sensitive to this hormone. Given by slow intravenous infusion to induce labour, oxytocin causes regular coordinated contractions that travel from fundus to cervix. Both amplitude and frequency of these contractions are related to dose, the uterus relaxing completely between contractions during low-dose infusion. Larger doses further increase the frequency of the contractions, and there is incomplete relaxation between them. Still higher doses cause sustained contractions that interfere with blood flow through the placenta and cause fetal distress or death.
- **Breast:** Oxytocin contracts myoepithelium of mammary alveoli and forces milk into the bigger milk sinusoids - 'milk ejection reflex' (milk letdown in cattle) is initiated by suckling so that it may be easily sucked by the infant. It has been used in milch cattle to facilitate milking.
- **CVS:** Conventional doses used in obstetrics have no effect on BP but higher doses cause vasodilatation leads to brief fall in BP, reflex tachycardia and flushing. This action is most marked in chicken - used for bioassay. The umbilical vessels are markedly constricted; oxytocin may help in their closure at birth.

- **Kidney:** Oxytocin in high doses exerts an ADH-like action-urine output is decreased;pulmonary edema can occur if large amounts of i.v. fluids and oxytocin are infused together. Conventional doses are without any effect.

Mechanism of action:

- Action of oxytocin on myometrium is independent of innervation. There are specific G-protein coupled oxytocin receptors which mediate the response mainly by depolarization of muscle fibres and influx of Ca^{2+} ions as well as through phosphoinositide hydrolysis and IP_3 mediated intracellular release of Ca^{2+} ions. The number of oxytocin receptors increases markedly during later part of pregnancy. Oxytocin increases PG synthesis and release by the endometrium which may contribute to the contractile response. Distinct subtypes of oxytocin receptors have been shown on the myometrium and the endometrium.

Clinical use:

- Oxytocin is used to induce or augment labour when the uterine muscle is not functioning adequately. It can also be used to treat postpartum haemorrhage.

Pharmacokinetic aspects

- Oxytocin can be given by intravenous injection or intramuscularly, but is most often given by intravenous infusion. It is inactivated in the liver and kidneys, and by circulating placental oxytocinase.

Unwanted effects of oxytocin

- Unwanted effects of oxytocin include dose-related hypotension (arising from its vasodilator action), with associated reflex tachycardia. Its antidiuretic hormone-like effect on water excretion by the kidney causes water retention and, unless water intake is curtailed, consequent hyponatraemia.

Ergometrine

- Ergot (*Claviceps purpurea*) is a fungus that grows on rye and contains a surprising variety of pharmacologically active substances. Ergot poisoning, which was once common, was often associated with abortion. In 1935, ergometrine was isolated and was recognised as the oxytocic principle in ergot.

Actions

- Ergometrine contracts the human uterus. This action depends partly on the contractile state of the organ. On a contracted uterus (the normal state following delivery),

ergometrine has relatively little effect. However, if the uterus is inappropriately relaxed, ergometrine initiates strong contraction, thus reducing bleeding from the placental bed (the raw surface from which the placenta has detached). Ergometrine also has a moderate degree of vasoconstrictor action per se.

- The mechanism of action of ergometrine on smooth muscle is not understood. It is possible that it acts partly on α adrenoceptors, like the related alkaloid ergotamine, and partly on 5-hydroxytryptamine receptors.

Pharmacokinetic aspects

- Ergometrine can be given orally, intramuscularly or intravenously. It has a very rapid onset of action and its effect lasts for 3-6 hours.

Clinical use:

- Ergometrine can be used to treat postpartum haemorrhage.
- A preparation containing both oxytocin and ergometrine is used for the management of the third stage of labour; the two agents together can also be used, prior to surgery, to control bleeding due to incomplete abortion.

Unwanted effects

- Ergometrine can produce vomiting, probably by an effect on dopamine D₂ receptors in the chemoreceptor trigger zone. Vasoconstriction with an increase in blood pressure associated with nausea, blurred vision and headache can occur, as can vasospasm of the coronary arteries, resulting in angina.

Prostaglandins:

Endogenous prostaglandins:

- Prostaglandins like PGE₂, PGF_{2a} and 15-methyl PGF_{2u} are potent endogenous uterine stimulants. The endometrium and myometrium have substantial prostaglandin-synthesising capacity, particularly in the second, proliferative phase of the menstrual cycle.
- Prostaglandin (PG) F_{2 α} is generated in large amounts, and has been implicated in the ischaemic necrosis of the endometrium that precedes menstruation (although it has relatively little vasoconstrictor action on many human blood vessels, in contrast to some other mammalian species). Vasodilator prostaglandins, PGE₂ and PGI₂ (prostacyclin), are also generated by the uterus.
- In addition to their vasoactive properties, the E and F prostaglandins contract the non-pregnant as well as the pregnant uterus. The sensitivity of uterine muscle to

prostaglandins increases during gestation. Their role in parturition is not fully understood, but as cyclo-oxygenase inhibitors can delay labour.

- Prostaglandins also play a part in two of the main disorders of menstruation: dysmenorrhoea (painful menstruation) and menorrhagia (excessive blood loss).

Prostaglandin preparations

- Prostaglandins of the E and F series promote coordinated contractions of the body of the pregnant uterus, while relaxing the cervix. E and F prostaglandins reliably cause abortion in early and middle pregnancy, unlike oxytocin, which generally does not cause expulsion of the uterine contents at this stage.
- The prostaglandins used in obstetrics are dinoprostone (PGE₂), carboprost (15-methyl PGF₂α) and gemeprost or misoprostol (PGE₁ analogues). Dinoprostone can be given intravaginally as a gel or as tablets, or by the extra-amniotic route as a solution. Carboprost is given by deep intramuscular injection. Gemeprost or misoprostol are given intravaginally.

Clinical use

- Dinoprostone given by the extra-amniotic route is used for late (second trimester) therapeutic abortion; given as vaginal gel, it is used for cervical ripening and induction of labour.
- Gemeprost, given as vaginal pessary following mifepristone, is used as a medical alternative to surgical termination of pregnancy (up to 63 days of gestation).

Unwanted effects

- Unwanted effects include uterine pain, nausea and vomiting, which occur in about 50% of patients when the drugs are used as abortifacients.
- Dinoprost may cause cardiovascular collapse if it escapes into the circulation after intra-amniotic injection. Phlebitis can occur at the site of intravenous infusion.
- When combined with mifepristone, a progestogen antagonist that sensitises the uterus to prostaglandins, lower doses of the prostaglandins (e.g. misoprostol) can be used to terminate pregnancy and side effects are reduced.

Drugs that inhibit uterine contraction

- Selective β₂-adrenoceptor agonists, such as **ritodrine** or **salbutamol**, inhibit spontaneous or oxytocin-induced contractions of the pregnant uterus. These uterine relaxants are used in selected patients to prevent premature labour occurring between 22 and 33 weeks of gestation in otherwise uncomplicated pregnancies. They can delay delivery by 48 hours, time that can be used to administer glucocorticoid therapy to the

mother so as to mature the lungs of the baby and reduce neonatal respiratory distress, and to optimise logistics such as making sure the baby is born in a facility with neonatal intensive care.

- Cyclo-oxygenase inhibitors (e.g. **indometacin**) inhibit labour, but their use could cause problems in the baby, including renal dysfunction and delayed closure of the ductus arteriosus, both of which are influenced by endogenous prostaglandins.
- An oxytocin receptor antagonist, **atosiban**, provides an alternative to a β 2-adrenoceptor agonist. It is given as an intravenous bolus followed by an intravenous infusion for not more than 48 hours. Adverse effects include symptoms of vasodilation, nausea, vomiting, and hyperglycaemia.

6. Bioassay

Bioassay may be defined as the determination of the concentration of a biologically active substance, of physical, chemical or biological origin, by using a biological indicator with reference to standard. Bioassay is comparative in nature.

Bioassay is the determination or estimation of the amount of biological activity in a unit quantity of the preparation. It is a process of determining relative potency of a substance or active principle of a substance by comparing its biological activity with that of a reference standard. Bioassay includes both quantitative assays of drugs as well as the application of qualitative biological tests. The purpose of bioassay is to determine the potency of a drug and hence it serves as the quantitative part of any screening procedure. Other purpose of bioassay is to standardize the preparation so that each contains uniform specified pharmacological activity.

Biological indicator:

The biological activity of a substance can be studied by using different experimental animals, isolated tissues of the experimental animals, immune cells or microorganisms are termed as biological indicator.

Biological standardization:

Comparison and adjustment of the strength of the unknown sample with that of the standard under rigidity controlled conditions is termed as bio-standardization. It is a process of increasing or decreasing the potency of a biologically active substance to match it with the biological activity of a reference standard. Matching of material of unknown potency with an

international/national standard objective of providing a reliable preparation for the use in therapeutics research. For example, matching of LD₅₀ of digitalis tincture (which contain variable quantities of the active principle) to the standard preparation.

Principles of Bioassay:

The basic principle of bioassay is to compare the test substance with the international standard preparation of the same and to find out how much test substance is required to produce the same biological effect, as produced by the standard. The followings are the principles of bioassay:

1. All bioassays (lab studies, toxicity studies, clinical studies) must be comparative & compared against a standard drug or preparation. The potency of biologically assayed compounds is compared with the activity of internationally accepted standards.
2. The standard and new drugs should be as far as possible identical to each other, then their dose response curve (DRC) will have the same slope and would be constant all along the response level.
3. The biological response should be closely related to the therapeutic use of the drug as possible. For example, in estimating the potency of insulin, blood glucose levels would be of the ideal index, but the method commonly used is the mouse convulsion method, in which the % of animals developing convulsions are recorded. Similarly for estimating digitaloid drug, the arrest of heart in pigeon or guinea pig is used as end point which is as the toxic effect of the drug and not the therapeutic effect.
4. An estimate of relative potency is made by comparing the log dose of the test and the log dose of the standard that produces an equal magnitude of effect.
5. The problem of biological variation must be minimized as far as possible. For that one should keep uniform experimental conditions and assure the reproducibility of the responses. The results of the test should be subjected to statistical analysis to minimize errors due to biological variations.

Applications of bioassay:

1. To standardize drugs of natural origin, especially when the chemical identity of the active has not been elucidated fully. e.g. parathyroid hormones, antitoxins etc.
2. To standardize those drugs from which no adequate chemical assay has been devised even though the chemical structure of the active principle has been established. e.g. hormones like insulin, oxytocin etc.
3. To standardize the drugs which are composed of a complex mixture of substances varying structure and activity. e.g. digitalis, posterior pituitary extract etc.

4. If the chemical assay is not a valid indication of the biological activity, e.g. due to lack of differentiation between active and inactive isomers.
5. To standardize when the drugs have same pharmacological actions but different chemical structures existing together. e.g. glycosides in digitalis preparation.
6. To estimate the dose of a drug required to produce a therapeutic or toxic response. e.g. calculation of ED₅₀, LD₅₀ etc.
7. When the physical property of rotation (dextro or levo) shows difference in action. e.g. d-Chloramphenicol is active. Levo adrenaline is 80 times more active than dextro.

b. Types of bioassay:

Bioassay may be broadly classified into two type depending upon the type of response recorded i.e. i) quantal bioassay and ii) graded bioassay.

(i) Quantal bioassay:

Quantal means the response is in the form of "all or none", i.e. either maximum response or no response. In this type of bioassay, there is no intermediate response. For example animal receiving a convulsant drug either show convulsions or does not. Examples of drugs assayed by quantal bioassay method are:

Digitalis: by cardiac arrest in guinea pig or pigeon.

d-Tubocurarine: by rabbit head drop method.

Insulin: by hypoglycaemic convulsions produced in mice.

Though the method is not very accurate, it is employed for comparison of threshold response and comparison of ED₅₀ or LD₅₀ values. The quantal bioassay is an end point method.

End point method: Here the threshold dose showing a positive effect is measured on each animal and the comparisons between two groups of animals are done i.e. one receiving standard and other the test compounds. e.g. bioassay of digitalis in cats. Here the cat is anaesthetized with chloralose and its blood pressure is recorded. The drug is slowly infused into the animal and the moment the heart stops beating and blood pressure falls to zero, the volume of fluid infused is noted down. Two groups of animals, one using standard digitalis and the other using test preparation of digitalis and then potency is calculated as follows:

$$\text{Concentration of unknown} = \frac{\text{Threshold dose of standard}}{\text{Threshold dose of test}} \times \text{Concentration of standard}$$

(ii) Graded bioassay:

Graded response means the response is proportional to the dose and response may lie between no response and the maximum response. These responses are based on the observations that there is a proportionate increase in the observed response with a subsequent increase in the concentration or dose. This procedure depends on the precision of assay demand, quality of the sample available, availability of experimental animals. Types of graded assay are: (a) Matching, (b) Bracketing, (c) Interpolation, (d) Multiple point bioassay (three point, four point, six point, eight point).

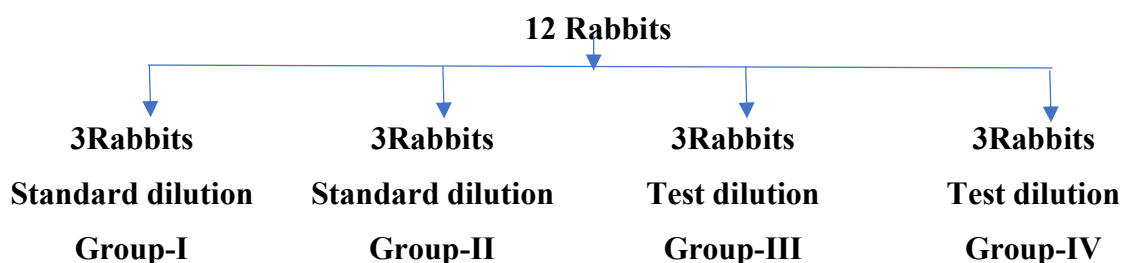

BIOASSAY OF INSULIN:

- Insulin is a hormone made by pancreatic β cell. Insulin is synthesised as pro-insulin in the endoplasmic reticulum and is processed to the biologically active form inside the secretory granules.
- Bioassay of insulin is generally carried out by rabbit method and mice method.
- Some of the other methods are: Rat diaphragm method, Epididymal fat pad of rats,
- **Standard preparation and unit:** It is pure, dry and crystalline insulin. One unit contains 0.04082 mg. This unit is specified by Ministry of Health, Government of India and is equivalent to international unit.
- **Preparation of standard solution:** Accurately weigh 20 units of insulin and dissolve it in normal saline. Acidify it with HCl to pH 2.5. Add 0.5% phenol as preservative. Add 1.4% to 1.8% glycerin. Final volume should contain 20 units/ml. Store the solution in a cool place and use it within six months.
- **Preparation of test sample solution:** The solution of the test sample is prepared in the same way as the standard solution.

1) Rabbit method:

- **Selection of rabbits:** They should be healthy, weighing about 1800-3000 gms. They should then be maintained on uniform diet but are fasted for 18 hrs. before assay. Water is withdrawn during the experiment.
- **Standard and Sample Dilutions:** These are freshly prepared by diluting with normal NaCl solution so as to contain 1 unit/ml and 2 units/ml.

- **Doses:** The dose which can produce suitable fall in blood sugar level is calculated for the standard.
- **Principle:** The potency of a test sample is estimated by comparing the hypoglycemic effect of the sample with that of the std. preparation of insulin. Any other suitable method can also be used.
- **Experimental Procedure:** Animals are divided into 4 groups of 3 rabbits each. The rabbits are then put into an animal holder. They should be handled with care to avoid excitement.
- **First part of the Test:** A sample of blood is taken from the marginal ear vein of each rabbit. Presence of reducing sugar is estimated per 100 ml of blood by a suitable chemical method. This concentration is called 'Initial Blood Sugar Level'.
- The four groups of rabbits are then given sc. injections of insulin as follows:

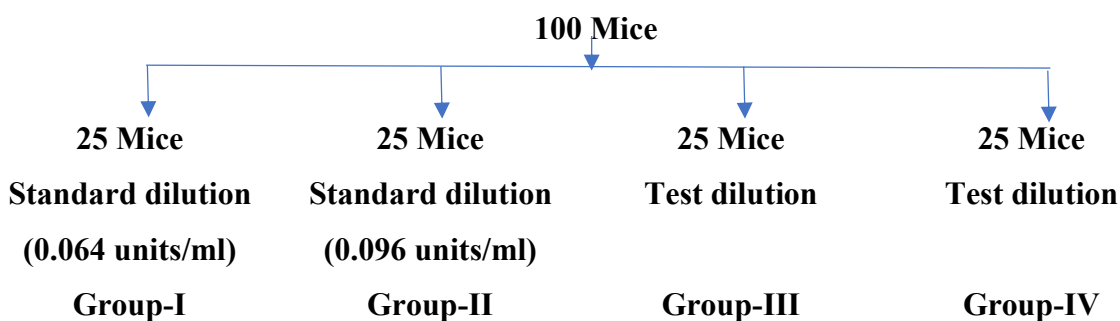

- From each rabbit, a sample of blood is withdrawn up to 5 hrs. at the interval of 1 hr. each. Blood sugar is determined again. This is known as 'Final Blood Sugar Level'.
- **Second part of the test (Cross over test) :** The same animals are used for the second part. The experiment can be carried out after one week. Again they are fasted and initial blood sugar is determined. The grouping is reversed, that is to say, those animals which received the standard are given the test and those which received the test are now given the standard. Those animals which received the less dose of the standard are given the higher dose of the test sample and vice-versa. This test is known as 'Twin Cross Over Test'.
- Mean percentage of decrease in blood sugar of first part and second part is calculated.

2) Mouse Method:

- Mice show characteristic convulsions after s.c. inj. of insulin at elevated temperatures. The percentage convulsions produced by the test and standard preparations are compared.

- **Experimental procedure:** Minimum 100 mice weighing between 18-22gms. of the same strain are used. They should be maintained on constant diet. They should be fasted 18 hrs. prior to the experiment.
- **Standard and sample dilutions:** Dilutions are prepared with sterile saline solution, so as to contain 0.064 units/ml. (std dilution I) and 0.096 units/ml. (std. dilution II). Similarly, test sample solutions are also prepared.
- Mice are divided into 4 groups each containing 25 mice and insulin is injected s.c. as follows:

- Mice are put in an air incubator at 33°C and observed for one and a half hour.
- The mice which convulse or die are taken out of the incubator and observed. These mice usually convulse severely but failure of the animal to upright itself when placed on its back, should as well be considered as convulsion.
- Convulsive mice may be saved by an inj. Of 0.5 ml of 5% dextrose solution.
- Percentage convulsions produced by test samples are compared with those of the standard sample. Those animals which survive may be used again for another experiment after an interval of one week.

BIOASSAY OF OXYTOCIN:

- Oxytocin is a peptide hormone and Neuropeptide. Oxytocin is normally produced by the paraventricular nucleus of the hypothalamus and released by the posterior pituitary.
- Oxytocin is a natural hormone that causes the uterus to contract. Oxytocin is used to induce labor or strengthen labor contractions during childbirth, and to control bleeding after childbirth.
- Oxytocin is also used to stimulate uterine contractions in a woman with an incomplete or threatened miscarriage.
- Different bioassay methods used for oxytocin are
 - By contraction of the rat uterus

- By depression of the blood pressure in chicken
- By measurement of milk ejection pressure in a lactating rat etc.

Principle:

- The potency of oxytocin injection is determined by comparing its activity with that of the standard preparation of oxytocin under the conditions of the following method of assay.

Standard preparation:

- The standard preparation is consisting of a freeze dried preparation of oxytocin with human albumin and citric acid (supplied in ampoules containing 12.5 units) or any other suitable preparation, the potency of which had been determined in relation to the International standard.
- The Unit is the specific oxytocin activity corresponding to that yielded by 0.0005 g of the Standard preparation.
- The standard preparation is as per the 4th international standard for Oxytocin, established in 1978.

Experimental Methods:**1) By contraction of the rat uterus:**

- Use female rats weighing between 120 and 200 g. Immediately before the assay confirm the rat is in oestrous or prooestrus by vaginal smear.
- Inject 100 microgram of oestradiol benzoate intramuscularly 18-24 hours before the assay. Kill the rat and suspend one horn of the uterus in a bath containing a solution of the following composition:

Composition	(% w/v)
Sodium chloride	0.662
Potassium chloride	0.045
Calcium chloride	0.007
Sodium bicarbonate	0.256
Disodium hydrogen phosphate	0.029
Sodium dihydrogen phosphate	0.003
Magnesium chloride	0.010
Dextrose	0.050

- Maintain the bath at a temperature of 32° C so that spontaneous contraction of the uterus are abolished and preparation maintain its sensitivity.
- Oxygenate the solution with a mixture of 95% of oxygen and 5% of carbon dioxide.

- Record the contractions of the muscles produced by the addition to the bath of two doses of the Standard Preparation suitably diluted with the above solution. The doses should be such as to produce clearly discriminated, submaximal contractions. The required doses normally lie between 10 and 50 micro Units per ml of bath liquid.
- When maximal contraction has reached replace the bath liquid by a fresh solution.
- The doses should be added at regular intervals of 3 to 5 minutes depending upon the rate of recovery of the muscle.
- Dilute the preparation being examined so as to obtain the responses on the addition of two doses similar to those obtained with the Standard preparation.
- The ratio between the two doses of the preparation being examined should be the same as that between the two doses of the Standard Preparation and this ratio should be kept constant throughout the assay.
- The two doses of Standard preparation and the two doses of the test preparation should be given according to a randomized order or Latin square design and at least six responses to each should be recorded.
- Measure all the responses and calculate the result of the assay by statistical methods.

2) By depression of the blood pressure in chicken:

- Anaesthetize a young healthy adult cockerel weighing 1.2 to 2.3 kg with an anesthetic that will maintain a prolonged and constant high blood pressure.
- Expose the gluteus primus muscle in one thigh and cut and retract it to reveal the popliteal artery and crural vein.
- Cannulate the popliteal artery and record the blood pressure. Cannulate the crural or brachial vein.
- Prepare standard solution with saline so that the volume to be injected is between 0.1-0.5 ml.
- Inject 2 doses of standard solution into cannulated vein and record blood pressure. The doses should be such that as to produce clearly discriminated, precipitous, submaximal decreases in B.P.
- The required doses normally lie between 20 and 100 milli units.
- The interval between injections should be constant and lie between 3-10 minutes depending on the rate at which B.P. returns to normal.
- Dilute test sample before use with saline solution so as to obtain responses similar to those obtained with the standard preparation.

- The ratio between the two doses of the test preparation being examined should be same as that between the two doses of the standard preparation and the ratio should be kept constant throughout the assay.
- The two doses of Standard preparation and the two doses of the test preparation should be given according to a randomized order or Latin square design and at least six responses to each should be recorded.
- If animal rapidly become insensitive due to repeated injections of the solutions another animal must be used. Measure all responses and calculate the result by standard statistical methods.

3) By measurement of milk-ejection pressure in a lactating rat:

- Select a lactating rat, in the third to twenty-first day after parturition and weighing about 300 g separate it from the litter and 30 to 60 minutes later anaesthetise (for example, by the intraperitoneal injection of a solution of Pentobarbitone Sodium).
- Tie the rat to an operating table, maintained at 37, by its hind legs leaving the front legs free. Cannulate the trachea with a short polyethylene tube of internal diameter about 2.5 mm in such a manner so as to ensure a free airway; apply artificial respiration only if necessary.
- Cannulate an external jugular or femoral vein with a polyethylene tube of internal diameter about 0.4 mm which is filled with saline solution and closed with a pin.
- Shave the skin surrounding the inguinal and abdominal teats and excise the tip of one teat, preferably the lower inguinal teat. Insert a polyethylene tube of internal diameter about 0.3 mm and external diameter about 0.6 mm, to a depth sufficient to obtain appropriate measurement of pressure (3 to 10 mm depth), into the primary teat duct which opens onto the cut surface and tie firmly in place with a ligature.
- Connect this cannula with a suitable strain gauge transducer (such as that used for recording arterial blood pressure in the rat) and fill the whole system with a 3.8% w/v solution of sodium citrate or saline solution containing 50 Units of heparin sodium per ml to prevent clotting of milk.
- After cannulation, inject a small volume (0.05 to 0.2 ml) of this solution into the teat duct through the transducer to clear the milk from the tip of the cannula. (This procedure may be repeated during the assay should obstruction arise from milk ejected into the cannula).

- Clamp the strain gauge so that a slight tension is applied to the teat and its natural alignment is preserved and connect the gauge to a potentiometric recorder adjusted to give full-scale deflection for an increase in milk-ejection pressure of about 5.3 kPa.
- Inject all solutions through the venous cannula using a 1-ml syringe graduated in 0.01 ml and wash them in with 0.2 ml of saline solution.
- Prepare a solution of the Standard Preparation and a solution of the preparation being examined in saline so that the volume to be injected is between 0.1 ml and 0.4 ml.
- Choose two doses of the Standard Preparation such that the increase in milk-ejection pressure is about 1.35 kPa for the lower dose and about 2.7 kPa for the higher dose.
- As an initial approximation, a lower dose of between 0.1 and 0.4 milliUnit and an upper dose of 1.5 to 2 times this amount may be tried.
- Choose two doses of the preparation being examined with the same inter-dose ratio, matching the effects of the doses of the Standard Preparation as closely as possible.
- Inject the four doses (two doses of the Standard Preparation and two doses of the preparation being examined) at intervals of 3 to 5 minutes.
- The two doses of Standard Preparation and the two doses of the preparation being examined should be given according to a randomised block or a Latin square design and at least four responses to each should be recorded. Measure all the responses and calculate the result of the assay by standard statistical methods.

BIOASSAY OF VASOPRESSIN:

Biological Assay for Vasopressor Activity

Principle:

- The vasopressor activity is estimated by comparing the activity of the preparation being examined with that of the Standard Preparation of arginine vasopressin under the conditions of a suitable method of assay.

Standard Preparation:

- The Standard Preparation is the 1st International Standard for Arginine vasopressin, established in 1978, consisting of freeze-dried synthetic arginine vasopressin peptide acetate with human albumin and citric acid (supplied in ampoules containing 8.20 Units), or another suitable preparation the potency of which has been determined in relation to that of the International Standard.

Suggested Method:

- Inject slowly into the tail vein of a male albino rat weighing about 300 g a solution of a suitable alpha-adrenoceptor blocking agent. For example 10 ml per kg of body weight of a solution prepared by dissolving 5 mg of phenoxybenzamine hydrochloride in 0.1 ml of ethanol (95%), adding 0.05 ml of 1M hydrochloric acid and diluting to 5 ml with saline solution.
- After 18 hours, anaesthetise the rat with an anaesthetic that will maintain a prolonged and uniform blood pressure. After 45 to 60 minutes, tie the rat on its back to the operating table by its hind legs.
- Cannulate the trachea with a short polyethylene tube of external diameter about 2.5 mm and dissect a carotid artery ready for cannulation. Then cannulate the femoral vein close to the inguinal ligament.
- Retract the abdominal muscles to expose the inguinal ligament. Retract the superficial pudendal vein to one side and dissect the femoral vein towards the inguinal ligament from the corresponding artery.
- When dissecting, a deep branch reaching the femoral vein must be found and tied off to prevent bleeding during cannulation. Tie a short polyethylene cannula of external diameter about 1 mm into the femoral vein by two ligatures and join by a short piece of flexible tubing to a 1-ml burette with an attached thistle funnel containing saline solution at about 37.
- Firmly fix a wet absorbent cotton swab to the thigh so as to cover the incision and cannula.
- At this stage inject through the venous cannula 200 Units of heparin, dissolved in saline solution, per 100 g of body weight.
- Then tie in a carotid cannula of external diameter about 1 mm and connect by a column of saline solution containing heparin with a suitable pressure measuring device such as a mercury manometer of internal diameter about 2 to 3 mm.
- The central and peripheral nervous system including both vagus and associated sympathetic nerves is left intact. No artificial respiration is necessary.
- Taking care that no air is injected, inject all solutions through the venous cannula by means of a 1-ml syringe graduated in 0.01 ml and wash in with 0.2 ml of saline solution from the burette.
- Dilute the extract of the Standard Preparation and the preparation being examined with saline solution so that the volume to be injected is between 0.1 ml and 0.5 ml. Choose two doses of the Standard Preparation such that the elevation of the blood

pressure is about 4 kPa for the lower dose and about 7 kPa but always submaximal for the higher dose, the ratio of low to high dose being determined by the response and usually being 3 to 5.

- As an initial approximation doses of 3 and 5 milliUnits may be tried. Choose two doses of the preparation being examined with the same inter-dose ratio, matching the effects of the dose of the Standard Preparation as closely as possible.
- Inject doses at intervals of 10 to 15 minutes. The two doses of the Standard Preparation and the two doses of the preparation being examined should be given in a randomised block or a Latin square design and four to five responses to each should be recorded.
- Measure all the responses and calculate the result of the assay by standard statistical methods.

BIOASSAY OF ACTH:

- ACTH (Adrenocorticotrophic hormone, corticotropin) is polypeptide tropic hormone (39 amino acids) secreted by the anterior pituitary gland.
- ACTH stimulates the production of cortisol, a steroid hormone important for regulating glucose, protein and lipid metabolism, suppressing the immune system response, and helping to maintain blood pressure.

Official Preparations

- Corticotropin injection: Is a sterile solution, in a suitable diluent, of the polypeptide from the pituitary glands of mammals. Potency range should be 80.0 – 120.0 % of USP corticotropin units.
- Corticotropin for injection, antimicrobial agent. Repository corticotropin injection is corticotropin in a sterile solution of partially hydrolyzed gelatin and is intended for subcutaneous and intramuscular use. This solution has been adopted as the reference standard for the bioassay.
 - **Packing:** Preserve in single-dose or multiple-dose containers of Type-I glass.
 - **Storage:** Store in cold place.
 - **Labeling:** Injection recommends intravenous administration

Purpose and rationale

- This is a historical assay method. Administration of pituitary ACTH decreases the ascorbic acid present in the adrenals. The depletion of adrenal ascorbic acid is a function of the dose of ACTH administered. This relationship has been used for a quantitative assay of ACTH.

Solutions:

- Solution A: Five units of test or standard dissolved in 0.25 ml of 0.5% phenol solution and diluted with 8.1 ml of 15% gelatin solution (Now 0.5ml contain 300 mU ACTH).
- solution B: Three ml of solution A diluted with 6 ml gelatin solution. Now concentration reduced to 100 mU ACTH/ 0.5 ml.
- solution C: Again 3 ml of solution B diluted with 6 ml of gelatin solution, the resulting solution contains 33 mU ACTH/ 0.5 ml.

Procedure

- Male Wistar rat (100-200 g) are hypophysectomized (pituitary gland removed by surgery) one day prior to the test.
- For one test with 3 dose of test preparation and standard solution used for the study.
- Number of hypophysectomized rats required: at least 36(preferably 60).
- The hypophysectomized rats are randomly distributed in to six groups. Each rat receives subcutaneous 0.5 ml of the various concentrations of test or standard.
- Three hours after injection, the animals are anesthetized and both adrenals removed, freed from extraneous tissue and weighed. The rats are sacrificed and the skull opened to verify completeness of hypophysectomy.
- The adrenals are homogenized in glass tubes contains 200 mg pure sand and 8.0 ml of 4% trichloroacetic acid and the ascorbic acid determined. (Roe and Kuether 1943).
- The potency ratio including confidence limits is calculated with the 3 + 3 point assay.

Ascorbic acid determination:**Reagents**

- 0.02% ascorbic acid solution
- 85 % sulfuric acid (9N H₂SO₄)
- 0.02 g/ml of dinitrophenolhydrazine in 9N H₂SO₄
- 0.06 g/ml of thiourea are dissolved in distilled water
- Charcoal

Preparation of 0.02% ascorbic acid solution

- 100 mg L-ascorbic acid are dissolved in 100 ml of 4% trichloroacetic acid (1mg/ml solution) (Solution A= 1 % solution)
- 2 ml of Solution A diluted in 10 ml of 4% trichloroacetic acid to achieve a 0.2% ascorbic acid solution (solution B)

- 1 ml of solution B diluted in 10 ml of 4% trichloroacetic acid to achieve a 0.02% ascorbic acid solution (solution C)

Preparation of other solutions

- Sulfuric acid (85%) is obtained by adding 900 ml concentrated sulfuric acid to 100 ml distilled water.
- Two g dinitrophenolhydrazine are dissolved in 100 ml 9 N H₂SO₄ (75 ml distilled water and 25 ml concentrated sulfuric acid).
- Six g thiourea are dissolved in 100 ml distilled water.

Calibration

- Trichloroacetic acid (4%) is added to 0.0, 0.5, 1.0, 2.0, 3.0, 4.0, 6.0, 8.0 ml of the 0.02% ascorbic acid solution (solution C) and 1.0, 1.5 and 2.0 ml of the 0.2% ascorbic acid solution to reach a final volume of 8.0 ml (Solution B).
- 100 mg charcoal is added to each sample and thoroughly mixed by shaking for 1 min.
- After 5 min the solutions are filtered.
- An aliquot of 0.1 ml of the 6% thiourea solution is added to 2.0 ml of the filtrate followed by 0.5 ml dinitrophenylhydrazine solution.
- The mixture is shaken and heated for 45 min at 57°C in a waterbath.
- The solutions are placed in an ice-cold water bath and with further cooling 2.5 ml of the 85% sulfuric acid are added.
- The calibration curve is established at a wave length of 540 nm using the solutions without ascorbic acid as blank.

BIOASSAY OF d-TUBOCURARINE:**1. Rabbit Head-drop Method :****Principle:**

- d-Tubocurarine hydrochloride is injected into the marginal vein of a rabbit's ear till the rabbit's neck muscles are relaxed such that the animal cannot hold its head up. The total amount of test sample required to produce the endpoint is compared with the total amount of the standard sample required to produce similar endpoint.

Selection of Rabbits:

- Rabbits weighing 2 kg are used. Animals should be free from disease, obtained from a healthy colony and should be accustomed with the experimental procedure.

Experimental Procedure:

- Rabbit is placed in a holder with its head protruding outside. The head should be freely movable.
- Minimum 8 rabbits are used. They are divided into two groups each containing 4 rabbits.
- First group will receive standard sample and the second group will receive the sample under test. d-Tubocurarine solution is injected at a constant speed by infusion apparatus through the marginal vein.
- Injection should be given at a rate of 0.4ml/min and should take about 10 min. Dose 0.012% w/v in saline.
- Infusion is continued till the rabbit will not be in a position to hold its head erect or there will be no response by focusing light on the eyes. Rabbits recover immediately from the effect of curarization.
- During the experiment there is a possibility of respiratory embarrassment which is treated by injecting neostigmine methyl sulphate (0.05 mg.) and atropine sulphate immediately through the marginal ear vein.
- Cross-over test is carried out to minimize biological error due to animal variation.
- Those rabbits which received the standard sample on the first day will be given test sample on the second day of experiment and vice versa.
- Mean dose which produces head drop of the test sample is compared with the mean dose of standard preparation.

2. Frogs Rectus Abdominis muscle Preparation:

- A frog is pithed and laid on its back on a cork covered board to which it is pinned. The skin covering the abdomen is cut away and the rectus abdominis muscle of one side is dissected from the pelvic girdle to its insertion in the cartilage of the pectoral girdle.
- The muscle is then pinned to the cork by four pins to keep its normal length while a thread is sewn through each end.
- It is then mounted in the organ bath containing frog's Ringer solution which contains: NaCl, 6.5gm.; KCl, 0.29 gm.; CaCl₂, 0.24 gm.; NaHCO₃, 0.4 gm.; glucose, 1.5 gm. and distilled water 2000 ml.

- Oxygenation is carried out to keep the tissue alive. The muscle is stabilized for 30-45 min. in order to get critical quantitative response.
- The responses are recorded using isotonic frontal writing lever with 1 G. tension.
- Two similar contractions with the same concentration of acetylcholine are obtained.
- Three doses of the standard sample and one intermediate dose of the test sample are selected and the reduction in height of contraction induced by acetylcholine is noted down.
- Acetylcholine contraction is recorded on slow moving drum for 90 second. d-Tubocurarine is allowed to act for 30 sec.
- The percentage reduction at each dose levels is calculated and log dose response curve of the standard drug is plotted. A linear response will be obtained. The potency of test sample is calculated from the standard curve.

BIOASSAY OF DIGITALIS:

Principle:

- Potency of the test sample is compared with that of the standard preparation by determining the action on the cardiac muscle.

Standard Preparation and Units:

- The standard preparation is a mixture of dried and powdered digitalis leaves (1 unit = 76 mg.)

Preparation of Extracts:

- Exact amount of the powder is extracted with dehydrated alcohol in a continuous extraction apparatus for six hours. The final extract should contain 10 ml (5 ml. alcohol + 5 ml. water) per 10 g. of digitalis powder. It should be stored in between 5°C and – 5°C.

1. Guinea-pig Method (Endpoint method):

- Standard and test sample extracts are diluted with normal saline in such a way that 1 g of digitalis powder is diluted to 80 ml.
- A guinea pig is anaesthetized with a suitable anaesthetic. It is dissected on the operation table. The jugular vein is traced out by removing adhering tissues and cannulated by means of venous cannula. A pin is inserted in the heart, such that it gets inserted in the apex of the heart. In this way, we can observe the heart beats by up and down movements of the pin.

- The injection is continued through venous cannula until the heart is arrested in systole. The amount of extract required to produce this effect is taken as the lethal dose of the extract.
- Another set of 19 animals of the same species are used for this experiment and the average lethal dose is determined. It is not necessary to determine the lethal dose of the standard during each time of the experiment. But it should be occasionally checked.
- The lethal dose of the test sample is determined in a similar way using minimum 6 guinea-pigs of the same strain.
- The potency of the test sample is calculated in relation to that of the std. preparation by dividing the average lethal dose of the sample to the test and expressed as units per gram.

2. Pigeon Method

- Minimum 6 pigeons are used for testing each sample. The weight of the heaviest pigeon should not exceed twice the weight of the lightest pigeon. Food is withheld 16-28 hours before the experiment.
- Pigeons are divided on the basis of their sex, weight and breed, into two groups. They are anaesthetized with anesthetic ether.
- One side of the wing is dissected and the alar vein is cannulated by means of a venous cannula. Dilutions are made with normal saline.
- The test sample and standard sample is infused through cannula. In pigeons, stoppage of heart is associated with a characteristic vomiting response called 'emesis'.
- The milk from the crop sac of pigeons is being ejected out. This may be taken as the end point response of digitalis.
- The lethal dose per kg. of body weight is determined for each pigeon.
- The potency of the test sample is determined by dividing the mean lethal dose of standard by the mean lethal dose of the test sample.

BIOASSAY OF HISTAMINE:

- Histamine is present in almost all the animal tissues mostly within mast cell and basophil granules. Tissues rich in histamine are skin, gastric and intestinal mucosa, lungs, liver and placenta.
- Non-mast cell histamine is present in brain, epidermis, gastric mucosa and growing regions. Histamine is also present in blood, most body secretions, venoms and pathological fluids. It is now known to play important physiological roles. Histamine

produces effects by acting on the histamine receptors (H₁, H₂, H₃ and H₄) present on target cells.

- Bioassay of histamine on isolated guinea pig ileum can be determined by graded bioassay procedure i.e. i) Matching bioassay, ii) Interpolation bioassay, iii) Bracketing assay, iv) Multiple point assays.
- Bioassay of histamine in biological samples can be studied by using different bioassay methods. Depending upon pharmacological action, histamine can be assayed by:
 - Contractile effect of isolated ileum of guinea pig,
 - Contractile effect of uterus of guinea pig and
 - Fall in blood pressure of anaesthetized and atropinized cat. Guinea pig's uterus

Bioassay of histamine using guinea pig ileum:

Principle:

- Guinea pig ileum is very useful preparation for the bioassay methods. It is more sensitive to histamine. Contractile response of histamine to ileum is due to presence of H₁ receptor.

Preparation of Standard and other solution:

- Prepare the stock of Tyrode solution. Also prepare the standard stock solution of histamine (1 mg/ml) and then different concentrations of histamine by serial dilution method.

Procedure:

- Sacrifice the 24 hr fasted guinea pig by stunning on the head and carotid bleeding. Fix the animal on the dissecting board by tying its legs. Open the abdominal cavity by a small horizontal cut followed by vertical midline incision and expose the abdominal organs.
- Trace the ileocaecal junction by lifting the caecum, then go upwards up to 8 cm from the junction and cut the 2-3 cm long segment of ileum muscle (excluding the terminal 5-8 cm, contains excess of excitatory α -adrenergic receptor, which may interfere in the study).
- Immediately place it in a petri dish containing aerated warm Tyrode solution. Slowly remove the mesentery attached to the muscle and then gently clean the lumen of ileum by passing luke warm Tyrode solution through it with a pipette or syringe.
- Mount the preparation in the inner organ bath containing Tyrode solution (20 ml) maintained at 37°C. Tie the bottom end of the muscle to the hook of aeration tube and the upper end to the isotonic frontal lever by a thread without closing the lumen.

Adjust the magnification of response to 7-10 fold. Aerate the tissue with O₂ or carbogen slowly (40-60 bubbles per minutes).

- Stabilize the tissue for 30 min by applying a tension of 0.5 g weight attached to the lever, during which wash the tissue with fresh Tyrode solution once in every 10 min.
- Use 5 min time cycle with contact time of 30s for recording the contraction dependent responses of tissue due to histamine on the smoked drums.
- Record the responses of standard and test compounds.
- Record the responses of test compound i.e. unknown concentration of histamine with gradually increasing volume, till obtaining a response (T) which would lie on the linear portion (30-70%) of the CRC. Fix the response obtained due to volume of T.
- Record the graded responses of standard solution and test solution of histamine.
- The potency of the test sample is calculated in relation to that of the std. preparation by dividing the average lethal dose of the sample to the test and expressed as units per gram.

BIOASSAY OF 5-HT:

- 5-Hydroxytryptamine (5HT) is the biologically active local hormone, low molecular weight, and also an important neurotransmitter in the brain and periphery.
- It was first detected in serum (serotonin) and enterochromaffin cells of gut mucosa (enteramine), and later both were identified to be 5HT. Today the terms 5HT and serotonin are used interchangeably.
- About 90% of body's content of 5-HT is localized in the intestines; most of the rest is in platelets and brain. It is also found in wasp and scorpion sting, and is widely distributed in invertebrates and plants (banana, pear, pineapple, tomato etc.).
- The concentration of 5-HT in biological samples can be assayed by: Isolated fundus strip of rat stomach, Isolated terminal colon of rat, Isolated rat uterus, Perfused rabbit ear.

Isolated fundus strip of rat stomach

Principle:

- Rat fundus preparation is a very sensitive tissue for the bioassay methods and is useful to study the action of several substances like 5-HT, ACh, PGE₂ and bradykinin. Fundus strip preparation is slow contracting muscle. Fundus part of stomach can be easily identified by its grey colour and situated above the pink coloured thick pyloric part. A zig-zag preparation of the fundal strip is prepared so as to expose maximum portion of the tissue to drug.

Preparation of Standard and other solution:

- Prepare the stock of Krebs solution. Prepare the standard stock solution of serotonin (1 mg/ml) and then different concentrations of serotonin by serial dilution method.

Procedure:

- Sacrifice the 24 hr fasted rat by stunning on the head and carotid bleeding. Fix the animal on the dissecting board by tying its legs. Open the abdominal cavity by a small horizontal cut followed by vertical midline incision and expose the abdominal organs.
- Identify the stomach and separate it from the abdomen by gently cutting its cardiac and pyloric end. Place it in a petri dish containing aerated warm Krebs solution.
- Incise the fundus of the stomach (upper grey part) from pyloric part (pink and thick part). Cut the fundus from the lesser curvature and open it longitudinally. Then cut the fundus at the midline into two equal parts. Give alternate transverse cuts (zig-zag cut) on opposite sides of the muscle to make a fundal strip preparation (as shown in fig. 9.1).
- Mount the preparation in the inner organ bath containing Krebs solution (20 ml) maintained at 37°C. Tie the bottom end of the muscle to the hook of aeration tube and the upper end to the isotonic frontal lever by thread. Adjust the magnification of response to 10-15 fold. Aerate the tissue with O₂ or carbogen slowly (40-60 bubbles per minutes).
- Apply 1 g load and stabilize the tissue for 30 min during which wash the tissue with fresh Krebs solution once in every 10 min.
- Use a 5 min time cycle with contact time of 90s (since the fundus strip muscle contracts slowly and relaxes slowly) for recording the contraction due to serotonin.
- Record the graded responses of standard solution and test solution of serotonin.
- The potency of the test sample is calculated in relation to that of the std. preparation by dividing the average lethal dose of the sample to the test and expressed as units per gram.

ANTI-ULCER DRUGS

PEPTIC ULCER

An Ulcer is ...

- **Erosion in the lining** of the stomach or the first part of the small intestine, an area called the duodenum.
- Ulcers damage the **mucosa** of the alimentary tract, which extends through the **muscularis mucosa** into the **sub mucosa** or deeper.

Ulcers that form in the stomach are called gastric ulcers; in the duodenum, they are called duodenal ulcers. Both types are referred to as peptic ulcers.

PEPTIC ULCER

PATHOGENESIS OF PEPTIC ULCER DISEASE

IMBALANCE:

AGGRESSIVE FACTORS

- **Acid**
- **Pepsin**
- **Helicobacter pylori**
- **NSAIDS**

DEFENSIVE FACTORS

Prostaglandins

Mucosal blood flow

Mucous gel layer

HCO₃

Epithelial junctions

Regeneration of the epithelial layer

Epidermal growth factor

Key: GR—Gastrin receptor; ST_2 —Somatostatin receptor; P—Proton pump (H^+/K^+ -ATPase); S—Symport carrier for K^+ and Cl^- ; A—Antiport carrier for HCO_3^- and Cl^- ; CA—Carbonic anhydrase; PK^* —Protein kinase activated; AC—Adenylate cyclase; H—Histamine (its receptor H_2); ECL—Enterochromaffin like cells

PHYSIOLOGY OF GASTRIC ACID SECRETION

Gastric acid secretion is a complex, continuous process in which multiple central and peripheral factors contribute to a common endpoint secretion of H^+ by parietal cells.

Neuronal (acetylcholine, Ach), paracrine (histamine), and endocrine (gastrin) factors all regulate acid secretion.

Their specific receptors (M_3 , H_2 , and CCK_2 receptors, respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach.

The H_2 receptor is a GPCR that activates the G_s -adenyl cyclase –cyclic AMP-PKA pathway.

Ach and gastrin signal through GPCRs that couple to the G_q -PLC- IP_3 - Ca^{2+} pathway in parietal cells .

In parietal cells , the cyclic AMP and the Ca^{2+} dependant pathways activate H^+,K^+ -ATPase (the proton pump), which exchanges hydrogen and potassium ions across the parietal cell membrane

PATHOPHYSIOLOGY

APPROACHES FOR THE TREATMENT OF ULCER

1. Reduction of gastric acid secretion

A) H₂ antihistaminics:

Cimetidine, ranitidine, famotidine, roxatidine

B) Proton pump inhibitors:

Omeprazole, esomeprazole, lansoprazole, pantoprazole, rabeprazole, dexrabeprazole

C) Anti cholinergic drugs:

Pirenzapine, propantheline, oxyphenonium

D) Prostaglandin analogue:

misoprostol

2. Neutralization of gastric acid

A) **Systemic** : Sodium bicarbonate, sodium citrate

B) **Non systemic**: Magnesium hydroxide, mag trisilicate, aluminium hydroxide gel, magaldrate, calcium carbonate

3. Ulcer protective :

Sucralfate, colloidal bismuth subcitrate

4. Anti H-pylori drugs:

Clarithromycin, metronidazole, amoxicillin, tinidazole, tetracycline

HISTAMINE ANTAGONIST

Cimetidine

.Histamine antagonists inhibit the action of histamine on the acid-producing cells of the stomach and reduce stomach acid

H₂RA Mechanism of Action

Del Valle, et al. eds. *Textbook of Gastroenterology*. 4th ed.; 2003,1323.

HISTAMINE ANTAGONIST

First class of highly effective drugs for acid peptic disease but surpassed by proton pump inhibitors

Cimetidine was the first to introduce in the market and described as prototype

Pharmacological actions:

1. H₂ blockade:

Block histamine induced gastric secretion, cardiac stimulation, uterine relaxation

No effect on H₁ responses because they are selective

2. Gastric secretion:

- ✓ Marked inhibition of gastric secretion
- ✓ All phase are suppressed dose dependently.
- ✓ Secretory response to not only histamine but also Ach, gastrin, insulin, alcohol, food are attenuated
- ✓ The volume, pepsin content and intrinsic factor secretion are reduced
- ✓ They don't have any direct action on gastric or oesophageal motility or on LES tone

PHARMACOKINETICS

Adequately absorbed orally,

Bioavailability is 60-80%

Undergoes first pass metabolism

No interference by presence of food

Crosses placenta and reaches milk

Poor BBB penetration

About 2/3 of dose is excreted unchanged in urine/bile

Elimination $t_{1/2}$ is 2-3hr

Dose reduction is needed in renal failure

CIMETIDINE

SIDE EFFECTS;

It include constipation, diarrhea, fatigue, headache, insomnia, muscle pain, and vomiting.

Major side effects:

- Bowel upset,
- Dry mouth,
- Rashes,
- Gynaecomastia,
- Impotence,
- Loss of libido,
- Decrease in sperm count

USES: It is used in treatment of

- ▢ Duodenal ulcer,
- ▢ Gastric ulcer,
- ▢ Stress ulcer,
- ▢ GERD,
- ▢ Zollinger ellison syndrome
- ▢ Prophylaxis of aspiration pneumonia

PROTON PUMP INHIBITORS

Proton pump inhibitors act by irreversibly blocking the **hydrogen/potassium adenosine triphosphatase enzyme (H⁺K⁺ATPase)** system of the gastric parietal cells.

The proton pump is the terminal stage in gastric acid secretion

PROTON PUMP INHIBITORS (OMEPRAZOLE)

Prototype member of this category

Overtaken H₂ blockers for acid peptic disorders

Dose dependant suppression of gastric secretion

No anticholinergic/ antihistaminergic

Powerful inhibitor of gastric acid secretion both resting and as well as stimulated

No much action on pepsin, juice volume and gastric motility

MECHANISM OF ACTION

Inactive at neutral pH, but at <5 it rearranges to two charged cationic forms

React covalently with SH groups of $H^+K^+ATPase$ enzyme and inactivate it irreversibly

After absorption it diffuses and concentrates in parietal cell and then in acidic pH of canaliculi

Binds tightly covalently with enzyme of parietal cell confers high degree of selectivity

Acid secretion resumes only when new $H^+K^+ATPase$ molecules are synthesized

PHARMACOKINETICS

All PPIs are administered enteric coated

Oral bioavailability is 50% due to acid lability

Food interferes with absorption

Should be taken 1 hour prior to meal

Highly plasma protein binding

Metabolised by CYP2C19 and CYP3A4

Plasma $t_{1/2}$ is 1 hour

Metabolites are excreted in urine

No dose modification is required in any impairment

Uses

Peptic ulcer

Bleeding peptic ulcer

Stress ulcer

GERD

Zollinger Ellison syndrome

Aspiration pneumonia

Adverse effects

Nausea, loose stools,
headache, abdominal pain,
muscle and joint pains

Rashes

Leucopenia

Hepatic dysfunction

Gynecomastia and erectile
dysfunction (lately observed)

HELICOBACTER PYLORI

1981 - **Robin Warren**, M.D.,
an Australian pathologist,
discovered numerous
bacteria living in tissue taken
during a stomach biopsy.

- Spiral urease-producing, Gram-negative bacteria always accompanied changes in the stomach lining

HELICOBACTER PYLORI

- Gram negative, Spiral bacilli
- Spirochetes
- Do not invade cells – only mucous
- Breakdown urea - ammonia
- Break down mucosal defense
- Chronic Superficial inflammation

SYMPTOMS OF H. PYLO

Abdominal pain

Feeling of Fullness

Indigestion

Feeling very hungry 1 to 3 hours after eating

Mild nausea

Pain Starts 2/3 hours after meals, or in the middle of the night

SYMPTOMS

Burning abdominal pain

Haematemesis

Melena

Nausea or vomiting

Unexplained weight loss

Anorexia

Abdominal fullness

DIAGNOSIS

Endoscopy:

Flexible tube fitted with camera is threaded down the esophagus in to stomach to see the ulcer by physician

Barium meal:

Barium liquid is drunk making ulcer visible on X-ray

View of a duodenal ulcer through the endoscope

Test for diagnosing H.pylori

- **Breath test** :by measuring the amount of CO_2 in exhaled breath.
- **Blood test**: by identifying H.pylori antibodies by ELISA test.
- **Stool test** :stool sample tested with H.pylori antigen.

ACETYL CHOLINE ANTAGONIST

PIRENZEPINE

➤ MECHANISM:

It selectively block M1 muscarinic receptors and inhibits gastric secretion.

Because of their relatively poor efficacy, side effects, and risk of blood disorders, they are rarely used today

AGENTS THAT ENHANCE MUCOSAL DEFENSE

Prostaglandin Analogs:

prostaglandins are produced in the gastric

mucosa and appear to serve a protective role by inhibiting acid secretion and promoting mucus

and bicarbonate secretion.

In addition, PGs inhibits gastrin production, increase mucosal blood flow and probably have an ill defined cytoprotective action.

DRUGS: Misoprostol

MISOPROSTOL

MECHANISM:

Misoprostol acts upon gastric parietal cells, inhibiting the secretion of gastric acid via G-protein coupled receptor-mediated inhibition of adenylate cyclase, which leads to decreased intracellular cyclic AMP levels and decreased pump activity at the apical surface of the parietal cell

○ Side effects

Diarrhea.

Other common side effects include: abdominal pain, nausea, flatulence, headache, dyspepsia, vomiting, and constipation.

ULCER PROTECTIVES

SUCRALFATE

MECHANISM:

Sucralfate is a locally acting **substance** that in an acidic environment ($\text{pH} < 4$),

reacts with **hydrochloric acid** in the **stomach** to form a cross-linking, **viscous**, **paste-like material** capable of acting as an **acid buffer** for as long as 6 to 8 hours after a single **dose**.

It also attaches to **proteins** on the surface of ulcers, such as **albumin** and **fibrinogen**, to form stable **insoluble** complexes.

These complexes serve as protective barriers at the ulcer surface, preventing further damage from **acid**, **pepsin**, and **bile**.

Side effects

The most common side effects seen are constipation. Less commonly reported include flatulence, cephalalgia (headache), xerostomia (dry mouth).

USES:

It is used in treatment of

Gastritis,

Stress ulcers.

ANTACIDS

Basic substances which neutralize the gastric acid and increase pH

Peptic activity is indirectly reduced if pH increase above 4 which dissociates below 5

Do not decrease acid production rather increase acid antral pH >4

Potency is generally expressed in term ANC

Aid neutralizing capacity : no of mEq of HCl that are brought to pH 3.5 in 15 mins by a unit dose of antacid

ANTACID

SYSTEMIC ANTACIDS

Sodium bicarbonate It is water soluble, acts instantaneously, but the duration of action is short. It is a potent neutralizer ($1 \text{ g} \rightarrow 12 \text{ mEq HCl}$), pH may rise above 7. However, it has several demerits:

- (a) Absorbed systemically: large doses will induce alkalosis.
- (b) Produces CO_2 in stomach \rightarrow distention, discomfort, belching, risk of ulcer perforation.
- (c) Acid rebound occurs, but is usually short lasting.

NON SYSTEMIC ANTACIDS

Insoluble and poorly absorbed basic substance react in stomach to form corresponding chloride salts

The chloride salts reacts with intestinal bicarbonate so that HCO_3^- is spread for absorption- no acid basic disturbances occurs

Magnesium hydroxide (milk of magnesia) with 30mEq HCl

Magnesium trisilicate :mg salts are having laxative action
generation osmotically active MgCl_2 induced cholecystokinin hormone

Aluminium hydroxide:

It ANC depends upon storage, its activity declines as storage time increases

Alum. hydrox. binds phosphate in the intestine and prevents its absorption—hypophosphatemia occurs on regular use. This may:

- (a) cause osteomalacia
- (b) be used therapeutically in hyperphosphatemia and phosphate stones.

Small amount of Al^{3+} that is absorbed is excreted by kidney. This is impaired in renal failure—aluminium toxicity (encephalopathy, osteoporosis) can occur.

SODIUM BICARBONATE (ANTACID)

It is water soluble, acts instantaneously, but duration of action is short. It is a **potent neutralizer**, pH may raises above 7.

Adverse reactions

It causes systemic alkalosis, gastric distention, rebound acidity and milk-alkali syndrome

Uses

It is restricted to casual treatment of heartburn and to treat acidosis

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

The book was set by Pine Tree Composition, Inc.
The editors were Shelley Reinhardt and Barbara Holton.
The production supervisor was Phil Galea.
The illustration manager was Charissa Baker.
The index was prepared by Kathy Pitcoff.
RR Donnelly was printer and binder.

This book is printed on acid-free paper.

shireen.banerji@rmpdc.org

Section II: Angiotensin Blockers & ACE Inhibitors; Vasodilators

James David Barry, MD

Fellow, Division of Medical Toxicology, and Clinical Instructor of Emergency Medicine, University of California, San Diego Medical Center

jdavebarr@aol.com

Section II: Phenytoin

Neal L. Benowitz, MD

Professor of Medicine and Chief, Division of Clinical Pharmacology and Toxicology, University of California, San Francisco; Associate Medical Director, California Poison Control System, San Francisco Division

nbeno@itsa.ucsf.edu

Section II: Anesthetics, Local; Antiarrhythmic Drugs; Antidepressants, General (Noncyclic); Antidepressants, Tricyclic; Beta-Adrenergic Blockers; Calcium Antagonists; Cardiac Glycosides; Chloroquine and Other Aminoquinolines; Cocaine; Ergot Derivatives; Lithium; Marijuana; Monoamine Oxidase Inhibitors; Nicotine; Nitrates and Nitrites; Nitroprusside; Pseudoephedrine, Ephedrine and Other Decongestants; Quinidine and Other Type IA Antiarrhythmic Drugs; Quinine; Vagor (PNU); Section III: Dopamine; Epinephrine; Norepinephrine

Kathleen Birnbaum, PharmD

Toxicology Management Specialist, Department of Clinical Pharmacy, University of California, San Francisco

kbirnbaum@calpoison.org

Section III: Insulin; Leucovorin Calcium

Paul D. Blanc, MD, MSPH

Professor of Medicine, University of California, San Francisco

blancp@itsa.ucsf.edu

Section II: Carbon Disulfide; Cyanide; Isocyanates; Manganese; Metal Fume Fever; Methemoglobinemia; Nitrogen Oxides; Section IV: Evaluation of the Patient with Occupational Chemical Exposure

Stephen C. Born, MD, MPH

Associate Clinical Professor, Division of Occupational and Environmental Medicine,

University of California, San Francisco

sborn@itsa.ucsf.edu

Section II: Dioxins, Ethylene Oxide

Alan Buchwald, MD

Consultant in Medical Toxicology and Medical Director, Occupational Health Center,

Dominican Santa Cruz Hospital, Santa Cruz, California

albuchwald955@pol.net

Section II: Copper

F. Lee Cantrell, PharmD

Assistant Clinical Professor of Pharmacy, School of Pharmacy, University of California,

San Francisco; Assistant Director, California Poison Control System, San Diego Division

fcantrel@ucsd.edu

Section II: Thyroid Hormone; Section III: Cyproheptadine; Folic Acid

Terry Carlson, PharmD

Toxicology Management Specialist, California Poison Control System, Fresno Division

tcarlson@wbmssoft.com

Section III: Naloxone and Nalmefene

Gregory Cham, MBBS, FRCSEd

Toxicology Fellow, California Poison Control System, San Francisco Division

gwmcham@yahoo.com

Section II: Phencyclidine (PCP) and Ketamine

Chulathida Chomchai, MD

Assistant Professor of Pediatrics, Department of Pediatrics, Faculty of Medicine, Siriraj

Hospital, Mahidol University, Bangkok, Thailand

sirirajpedstox@hotmail.com

Section II: Ipecac Syrup

Summon Chomchai, MD, MPH

Faculty of Medicine, Siriraj Hospital, Mahidol University, Bangkok, Thailand

thaitox@aol.com

Section II: Phosphine and Phosphides; Phosphorus

Richard F. Clark, MD

Professor of Medicine, University of California, San Diego; Director, Division of Medical

Toxicology and Medical Director, California Poison Control System, San Diego Division

Section II: Hymenoptera; Lionfish and Other Scorpaenidae; Scorpions; Snakebite; Section

III: Antivenom, Crotalinae (Rattlesnake); Antivenom, Latrodectus Mactans (Black Widow

Spider); Antivenom, Micrurus Fulvius (Coral Snake) and Exotic Antivenoms

Delia A. Dempsey, MD, MS

Assistant Adjunct Professor of Pediatrics, Medicine, and Clinical Pharmacy; Assistant

Medical Director, California Poison Control System, University of California, San Francisco

Section I: Special Considerations in Pediatric Patients; Section II: Bromides; Methyl

Bromide; Pentachlorophenol and Dinitrophenol

Jo Ellen Dyer, PharmD

Associate Clinical Professor of Pharmacy, University of California, San Francisco; Senior

Toxicology Management Specialist, California Poison Control System, San Francisco

Division

jodyer@itsa.ucsf.edu

Section I: Special Consideration in the Evaluation of Drug-Facilitated Assault; Section II:

Azide, Sodium; Gamma Hydroxybutyrate (GHB)

Andrew Erdman, MD

Clinical Pharmacology Fellow, University of California, San Francisco
andrewerdman@sbcglobal.net
Section II: Isoniazid (INH)

Gary W. Everson, PharmD

Toxicology Management Specialist, California Poison Control System, Fresno Division
geversen@calpoison.org
Section II: Phenol and Related Compounds; Section III: Mannitol

Thomas J. Ferguson, MD, PhD

Associate Clinical Professor of Internal Medicine, University of California, Davis; Medical Director, Cowell Student Health Center, University of California, Davis
tjferguson@ucdavis.edu
Section II: Chromium; Thallium

Frederick Fung, MD, MS

Clinical Professor of Occupational Medicine, University of California, Irvine; Chief Toxicologist, Sharp Rees-Stealy Medical Group, San Diego, California
fred.fung@sharp.com
Section II: Carbon Tetrachloride and Chloroform

Mark Galbo, MS

Specialist, California Poison Control System, San Francisco Division
mjgalbo@itsa.ucsf.edu
Section II: Naphthalene and Paradichlorobenzene; Warfare Agents – Chemical

Fabian Garza, PharmD

Doctor of Pharmacy, School of Pharmacy, University of California, San Francisco; Toxicology Management Specialist, California Poison Control System, Fresno Division
fgarza@calpoison.org
Section III: Methylene Blue

Richard J. Geller, MD, MPH

Assistant Clinical Professor, University of California, San Francisco School of Medicine; Medical Director, California Poison Control System, Fresno Division
Section II: Disulfiram; Selenium; Paraquat and Diquat; Section III: Atropine and Glycopyrrrolate; Pralidoxime (2-PAM) & Other Oximes

Colin S. Goto, MD

Attending Toxicologist, California Poison Control System, San Diego Division; Pediatric Emergency Medicine Physician, Children's Hospital and Health Center; Clinical Assistant Professor of Pediatrics, University of California, San Diego
cgoto@chsd.org
Section II: Hydrocarbons

Christine A. Haller, MD

Assistant Adjunct Professor of Medicine, University of California, San Francisco; Assistant Medical Director, California Poison Control System, San Francisco Division
dchaller@worldnet.att.net

Preface

Poisoning & Drug Overdose provides practical advice for the diagnosis and management of poisoning and drug overdose and concise information about common industrial chemicals.

The manual is divided into four sections and an index, each identified by a black tab in the right margin. **Section I** leads the reader through initial emergency management, including treatment of coma, hypotension, and other common complications; physical and laboratory diagnosis; and methods of decontamination and enhanced elimination of poisons. **Section II** provides detailed information for about 150 common drugs and poisons. **Section III** describes the use and side effects of about 60 antidotes and therapeutic drugs. **Section IV** describes the medical management of chemical spills and occupational chemical exposures and includes a table of over 500 chemicals. The **Index** is comprehensive and extensively cross-referenced.

The manual is designed to allow the reader to move quickly from section to section, obtaining the needed information from each. For example, in managing a patient with isoniazid intoxication, the reader will find specific information about isoniazid toxicity in **Section II**, practical advice for gut decontamination and management of complications such as seizures in **Section I**, and detailed information about dosing and side effects for the antidote pyridoxine in **Section III**.

ACKNOWLEDGMENTS

The success of the first and second editions of this manual would not have been possible without the combined efforts of the staff, faculty, and fellows of the San Francisco Bay Area Regional Poison Control Center, to whom I am deeply indebted. From its inception, this book has been a project by and for our poison center; as a result, all royalties from its sale have gone to our center's operating fund and not to any individual editor or author.

In January 1997, four independent poison control centers joined their talents and vision to become the California Poison Control System, administered by the University of California, San Francisco. With the third edition, the manual became a project of our statewide system, bringing in new authors and editors.

On behalf of the authors and editors of the fourth edition, my sincere thanks go to all those who contributed to the first three editions:

Timothy E. Albertson, MD, PhD (3rd ed)
Judith A. Alsop, PharmD (3rd ed)
Ilene Brewer Anderson, PharmD
(1st, 2nd and 3rd ed.)
Margaret Atterbury, MD (1st ed.)
Georgianne M. Backman (1st ed.)
John Balmes, MD (2nd & 3rd ed.)
Charles E. Becker, MD (1st & 2nd ed.)
Neal L. Benowitz, MD
(1st, 2nd & 3rd ed.)
Bruce Bernard, MD (1st ed.)
Paul D. Blanc, MD, MSPH
(1st, 2nd & 3rd ed.)
Christopher R. Brown, MD (3rd ed)
Randall G. Browning, MD, MPH (3rd ed)
James F. Buchanan, PharmD (1st ed.)
Alan Buchwald, MD (3rd ed)
Richard F. Clark, MD (3rd ed)

Kent R. Olson, MD (1st & 2nd ed.)
Michael O'Malley, MD, MPH (3rd ed.)
Gary Joseph Ordog, MD, (3rd ed)

John D. Osterloh, MD (1st, 2nd & 3rd ed.)
Gary Pasternak, MD (1st ed.)
Paul D. Pearigen, MD (3rd ed)
Brett A. Roth, MD (3rd ed)
Dennis J. Shusterman, MD, MPH (3rd ed)
Karl A. Sporer, MD (2nd & 3rd ed.)
S. Alan Tani, PharmD (2nd & 3rd ed.)
Mary Tweig, MD (1st ed.)
Peter H. Wald, MD, MPH (1st & 3rd ed.)
Jonathan Wasserberger, MD (3rd ed)
Janet S. Weiss, MD (3rd ed)
Saralyn R. Williams, MD (3rd ed)
Olga F. Woo, PharmD (1st, 2nd & 3rd ed.)
Evan T. Wythe, MD (1st, 2nd & 3rd ed.)
Peter Yip, MD (1st ed.)
Shoshana Zevin, MD (3rd ed)

We are also grateful for the numerous comments and suggestions received from colleagues, students, and the editorial staff at McGraw-Hill, which helped us to improve the manual with each edition.

Finally, a special thanks to Donna, Brad, Marlene, and Greg, for their patience, love, and support.

Kent R. Olson, MD, FACEP, FACMT, FAACT

San Francisco, California
September 2003

Contents

Authors.....	vi
Preface	xv
Section I. Comprehensive Evaluation & Treatment	1
This section provides a step-wise approach to the evaluation and treatment of coma, seizures, shock, and other common complications of poisoning and to the proper use of gastric decontamination and dialysis procedures.	
Section II. Specific Poisons & Drugs: Diagnosis & Treatment	66
Organized alphabetically, this section lists specific drugs and poisons, as well as the pathophysiology, toxic dose and level, clinical presentation, diagnosis, and specific treatment associated each substance.	
Section III. Therapeutic Drugs & Antidotes	404
This section provides descriptions of therapeutic drugs and antidotes discussed in Sections I and II, including their pharmacology, indications, adverse effects, drug interactions, recommended dosage, and formulations.	
Section IV. Environmental & Occupational Toxicology.....	510
This section describes the approach to hazardous materials incidents; the evaluation of occupational exposures; and the toxic effects, physical properties, and workplace exposure limits for over 500 common industrial chemicals.	
Index	631
The index includes generic drug and chemical names and numerous brand name drugs and commercial products.	

SECTION I. Comprehensive Evaluation and Treatment

► EMERGENCY EVALUATION AND TREATMENT

Kent R. Olson, MD

Even though they may not appear acutely ill, all poisoned patients should be treated as if they have a potentially life-threatening intoxication. Below is a checklist (Figure I-1) of emergency evaluation and treatment procedures. More detailed information on diagnosis and treatment for each emergency step is referenced by page and presented immediately after the checklist.

When you are treating suspected poisoning cases, **quickly review the checklist** to determine the scope of appropriate interventions and **begin needed life-saving treatment**. If further information is required for any step, turn to the cited pages for detailed discussion of each topic. Although the checklist is presented in a **sequential format**, many steps may be performed **simultaneously** (eg, airway management, naloxone and dextrose administration, and gastric lavage).

AIRWAY

- I. **Assessment.** The most common factor contributing to death from drug overdose or poisoning is loss of airway-protective reflexes with subsequent airway obstruction caused by the flaccid tongue, pulmonary aspiration of gastric contents, or respiratory arrest. All poisoning patients should be suspected of having a potentially compromised airway.
 - A. **Patients who are awake** and talking are likely to have intact airway reflexes, but should be monitored closely because worsening intoxication can result in rapid loss of airway control.
 - B. **In lethargic or obtunded patients**, the gag or cough reflex may be an indirect indication of the patient's ability to protect the airway. If there is any doubt, it is best to perform endotracheal intubation (see below).
- II. **Treatment.** Optimize the airway position and perform endotracheal intubation if necessary. Early use of naloxone (see pp 20 and 469) or flumazenil (see pp 20 and 446) may awaken a patient intoxicated with opiates or benzodiazepines, respectively, and obviate the need for endotracheal intubation. (**Note:** Flumazenil is **not** recommended except in very selected circumstances, as its use may precipitate seizures.)
 - A. **Position the patient and clear the airway** (see Figure I-2).
 1. **Optimize the airway position** to force the flaccid tongue forward and to maximize the airway opening. The following techniques are useful. **Caution:** Do **not** perform neck manipulation if you suspect a neck injury.
 - a. Place the neck and head in the **"sniffing" position**, with the neck flexed forward and the head extended (Figure I-2B).
 - b. Apply the **"jaw thrust"** to create forward movement of the tongue without flexing or extending the neck. Pull the jaw forward by placing the fingers of each hand on the angle of the mandible just below the ears (Figure I-2C). (This motion also provides a painful stimulus to the angle of the jaw, the response to which indicates the patient's depth of coma.)
 - c. Place the patient in a **head-down, left-sided position** that allows the tongue to fall forward and secretions or vomitus to drain out of the mouth (Figure I-2D).
 2. If the airway is still not patent, examine the oropharynx and **remove any obstruction or secretions** by suction, by a sweep with the finger, or with Magill forceps.

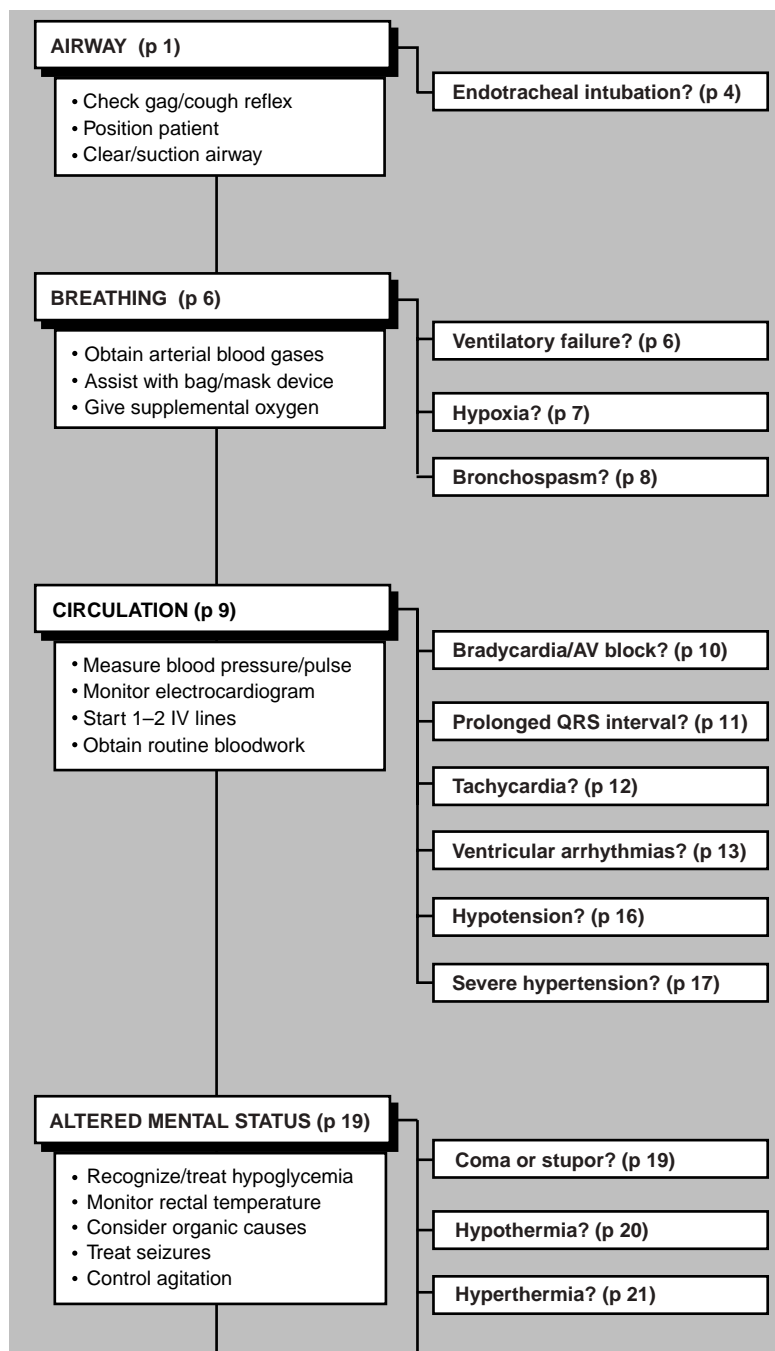

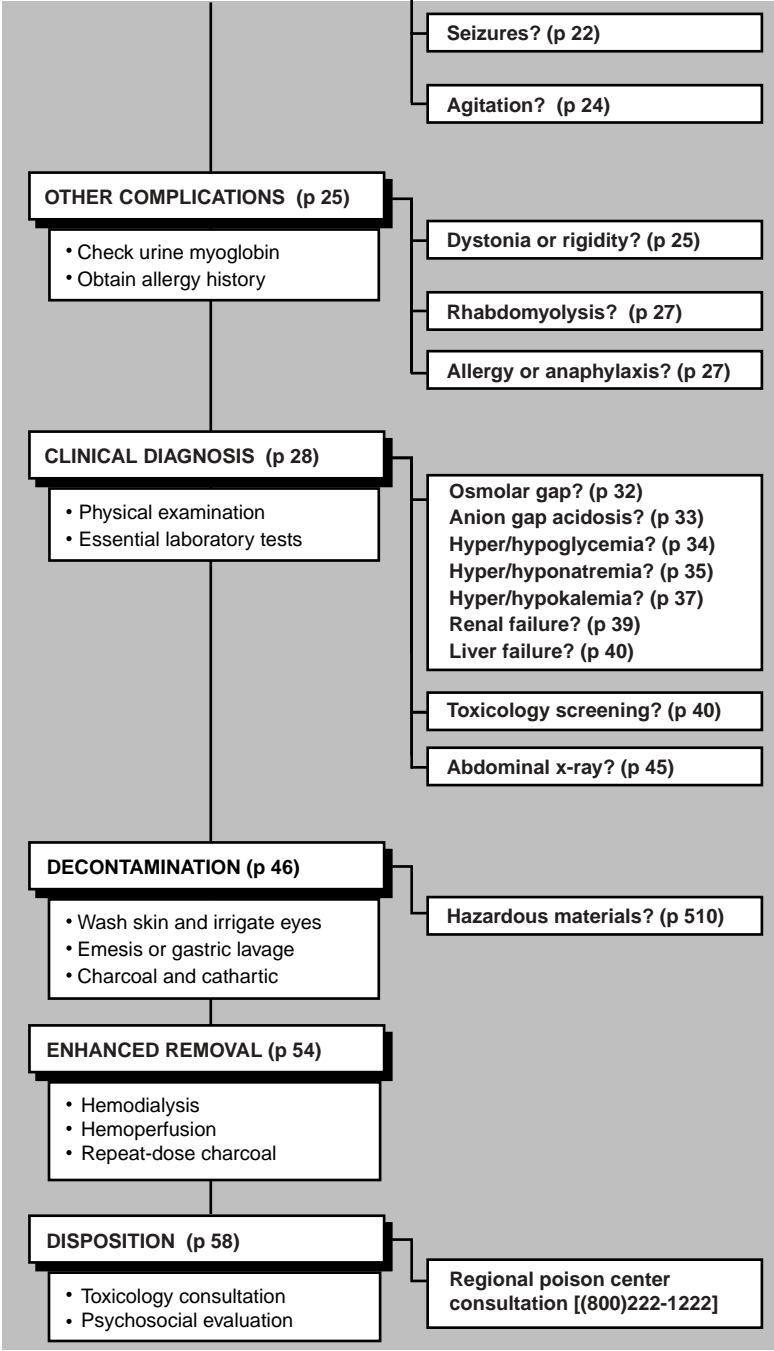

FIGURE I-1. Checklist of emergency evaluation and treatment procedures.

FIGURE I-2. Airway positioning. A: Normal position. B: "Sniffing" position. C: "Jaw thrust" maneuver. D: Left-side, head-down position, showing nasal and oral airway.

3. The airway can also be maintained with **artificial oropharyngeal or nasopharyngeal airway devices**. These are placed in the mouth or nose to lift the tongue and push it forward. They are only temporary measures. A patient who can tolerate an artificial airway without complaint probably needs an endotracheal tube.

B. Perform endotracheal intubation if personnel trained in the procedure are available. Intubation of the trachea provides the most reliable protection of the airway, preventing aspiration and obstruction and allowing for mechanically assisted ventilation. However, it is not a simple procedure and *should be attempted only by those with training and experience*. Complications include vomiting with pulmonary aspiration; local trauma to the oropharynx, nasopharynx, and larynx; inadvertent intubation of the esophagus or a main-stem bronchus; and failure to intubate the patient after respiratory arrest has been

induced by a neuromuscular blocker. There are two routes for endotracheal intubation: nasotracheal and orotracheal.

1. Nasotracheal intubation. In nasotracheal intubation, a soft flexible tube is passed through the nose and into the trachea, by using a “blind” technique (Figure I–3A).

a. Technique

- (1) Instill local anesthetic and insert a vasoconstrictor into the patient's nose before the procedure to limit pain and bleeding. Use phenylephrine spray and 2% lidocaine jelly or 3–4 mL of a 5% cocaine solution.
- (2) Pass the nasotracheal tube gently through the nose and into the nasopharynx. As the patient inspires, gently but firmly push the tube into the trachea. Success is usually marked by abrupt coughing.
- (3) Check breathing sounds to rule out accidental esophageal intubation or intubation of the right main-stem bronchus.
- (4) Secure the tube and fill the cuff balloon. (Tubes used for children do not have inflatable cuffs.)
- (5) Obtain a chest x-ray to confirm appropriate tube placement.

b. Advantages

- (1) May be performed in a conscious patient without requiring neuromuscular paralysis.
- (2) Once placed, it is usually better tolerated than an orotracheal tube.

c. Disadvantages

- (1) Perforation of the nasal mucosa with epistaxis.
- (2) Stimulation of vomiting in an obtunded patient.
- (3) Patient must be breathing spontaneously.
- (4) Anatomically more difficult in infants because of their anterior epiglottis.

2. Orotracheal intubation. In orotracheal intubation, the tube is passed through the patient's mouth into the trachea under direct vision (Figure I–3B).

a. Technique

- (1) If the patient is not fully relaxed (eg, if the jaw is not flaccid or neck mobility is restricted), induce neuromuscular paralysis with succinylcholine (1–1.5 mg/kg intravenously [IV]), rocuronium (0.6–1.2 mg/kg IV) or pancuronium (0.1 mg/kg IV), or another neuromuscular blocking agent (see p 472). **Caution:** In children, succinylcholine may induce excessive vagal tone, resulting in bradycardia or asystole. Patients with digitalis intoxication (see p 155) may have a similar response to succinylcholine. Pretreat with atropine (0.01 mg/kg IV),

FIGURE I–3. Two routes for endotracheal intubation. A: Nasotracheal intubation. B: Orotracheal intubation.

or use rocuronium, pancuronium, or another nondepolarizing neuromuscular blocker for paralysis. Also, a nondepolarizing agent is preferred if rhabdomyolysis or hyperkalemia is present.

- (2) Ventilate the patient manually with 100% oxygen while awaiting full paralysis (1–2 minutes for succinylcholine or rocuronium, 3–5 minutes for pancuronium).
- (3) Using a lighted laryngoscope, visualize the larynx and pass the endotracheal tube into the trachea under direct vision. Have an assistant apply firm pressure over the cricoid cartilage to prevent passive reflux of gastric contents into the oropharynx.
- (4) Check breathing sounds to rule out accidental esophageal intubation or intubation of the right main-stem bronchus.
- (5) Secure the tube and inflate the cuff balloon. (Tubes used for children do not have inflatable cuffs.)
- (6) Obtain a chest x-ray to confirm the appropriate tube position.

b. Advantages

- (1) Performed under direct vision, making accidental esophageal intubation unlikely.
- (2) Insignificant risk of bleeding.
- (3) Patient need not be breathing spontaneously.
- (4) Higher success rate than that achieved via the nasotracheal route.

c. Disadvantages

- (1) Frequently requires neuromuscular paralysis, creating a risk of fatal respiratory arrest if intubation is unsuccessful.
- (2) Requires neck manipulation, which may cause spinal cord injury if the patient has also had neck trauma.

Clancy M, Nolan J: Airway management in the emergency department. *Emerg Med J* 2002;19(1):2–3. [PMID: 11777859] (Review.)

BREATHING

Along with airway problems, breathing difficulties are the major cause of morbidity and death in patients with poisoning or drug overdose. Patients may have one or more of the following complications: ventilatory failure, hypoxia, or bronchospasm.

I. Ventilatory failure.

A. Assessment. Ventilatory failure has multiple causes, including failure of the ventilatory muscles, central depression of respiratory drive, and severe pneumonia or pulmonary edema. Examples of drugs and toxins that cause ventilatory failure and the causative mechanisms are listed in Table I–1.

TABLE I–1. SELECTED DRUGS AND TOXINS CAUSING VENTILATORY FAILURE^a

Paralysis of ventilatory muscles	Depression of central respiratory drive
Botulinum toxin (botulism)	Antihistamines
Neuromuscular blockers	Barbiturates
Nicotine	Clonidine and other sympatholytic agents
Organophosphates and carbamates	Ethanol and alcohols
Snakebite	Gamma hydroxybutyrate (GHB)
Strychnine and tetanus (muscle rigidity)	Opiates
	Phenothiazines and antipsychotic drugs
	Sedative-hypnotics
	Tricyclic antidepressants

^aAdapted in part, with permission, from Olson KR, Pentel PR, Kelly MT: Physical assessment and differential diagnosis of the poisoned patient. *Med Toxicol* 1987;2:52.

- B. Complications.** Ventilatory failure is the most common cause of death in poisoned patients.
1. Hypoxia may result in brain damage, cardiac arrhythmias, and cardiac arrest.
 2. Hypercarbia results in acidosis, which may contribute to arrhythmias, especially in patients with tricyclic antidepressant overdose.
- C. Differential diagnosis.** Rule out the following:
1. Bacterial or viral pneumonia.
 2. Viral encephalitis or myelitis (eg, polio).
 3. Traumatic or ischemic spinal cord or central nervous system (CNS) injury.
 4. Tetanus, causing chest wall muscle rigidity.
 5. Pneumothorax.
- D. Treatment.** Obtain measurements of arterial blood gases. Quickly estimate the adequacy of ventilation from the $p\text{CO}_2$ level; obtundation with an elevated or rising $p\text{CO}_2$ (eg, > 60 mm Hg) indicates a need for assisted ventilation. Do **not** wait until the patient is apneic or until the $p\text{CO}_2$ is above 60 mm to begin assisted ventilation.
1. Assist breathing manually with a bag-valve-mask device or bag-valve-endotracheal tube device until the mechanical ventilator is ready for use.
 2. If not already accomplished, **perform endotracheal intubation.**
 3. **Program the ventilator** for tidal volume (usually 15 mL/kg), rate (usually 12–15 breaths/min), and oxygen concentration (usually 30–35% to start). Monitor the patient's response to ventilator settings frequently by obtaining arterial blood gas values.
 - a. If the patient has some spontaneous ventilation, the machine can be set to allow the patient to breathe spontaneously with only intermittent mandatory ventilation (usually 10–12 breaths/min).
 - b. If the endotracheal tube has been placed only for airway protection, the patient can be left to breathe entirely spontaneously with blow-by oxygen mist (T-piece).

II. Hypoxia.

- A. Assessment.** Examples of drugs or toxins causing hypoxia are listed in Table I–2. Hypoxia can be caused by the following conditions:
1. **Insufficient oxygen** in ambient air (eg, displacement of oxygen by inert gases).
 2. **Disruption of oxygen absorption** by the lung (eg, resulting from pneumonia or pulmonary edema).

TABLE I-2. SELECTED CAUSES OF HYPOXIA^a

Inert gases	Pneumonia or noncardiogenic pulmonary edema
Carbon dioxide	Aspiration of gastric contents
Methane and propane	Aspiration of hydrocarbons
Nitrogen	Chlorine and other irritant gases
Cardiogenic pulmonary edema	Cocaine
Beta blockers	Ethchlorvynol (IV and oral)
Quinidine, procainamide, and disopyramide	Ethylene glycol
Tricyclic antidepressants	Mercury vapor
Verapamil	Metal fumes ("metal fumes fever")
Cellular hypoxia	Nitrogen dioxide
Carbon monoxide	Opiates
Cyanide	Paraquat
Hydrogen sulfide	Phosgene
Methemoglobinemia	Salicylates
Sulfhemoglobinemia	Sedative-hypnotic drugs
	Smoke inhalation

^aSee also Table I–1.

- a. **Pneumonia.** The most common cause of pneumonia in overdosed patients is pulmonary aspiration of gastric contents. Pneumonia may also be caused by intravenous injection of foreign material or bacteria, aspiration of petroleum distillates, or inhalation of irritant gases.
- b. **Pulmonary edema.** All agents that can cause chemical pneumonia (eg, irritant gases and hydrocarbons) can also cause pulmonary edema. This usually involves an alteration of permeability in pulmonary capillaries, resulting in **noncardiogenic** pulmonary edema (adult respiratory distress syndrome [ARDS]). In noncardiogenic pulmonary edema, the pulmonary capillary wedge pressure (reflecting filling pressure in the left ventricle) is usually normal or low. In contrast, **cardiogenic** pulmonary edema caused by cardiac-depressant drugs is characterized by low cardiac output with elevated pulmonary wedge pressure.

3. **Cellular hypoxia**, which may be present despite a normal arterial blood gas value.

- a. **Carbon monoxide** poisoning (see p 151) and **methemoglobinemia** (p 261) may severely limit oxygen binding to hemoglobin (and, therefore, the oxygen-carrying capacity of blood) without altering the pO_2 , because routine blood gas determination measures dissolved oxygen in the plasma but does not measure actual oxygen content. In such cases, only the direct measurement of oxygen saturation (not its calculation from the pO_2) will reveal decreased oxyhemoglobin saturation. **Note:** Pulse oximetry gives falsely normal or nearly normal results and is not reliable.

- b. **Cyanide** (p 177) and **hydrogen sulfide** poisoning (p 224) interfere with cellular oxygen utilization, resulting in decreased oxygen uptake by the tissues, and may cause abnormally high venous oxygen saturation.

B. **Complications.** Significant or sustained hypoxia may result in brain damage and cardiac arrhythmias.

C. **Differential diagnosis.** Rule out the following:

1. Erroneous sampling (eg, inadvertently measuring venous blood gases rather than arterial blood gases).
2. Bacterial or viral pneumonia.
3. Pulmonary contusion caused by trauma.
4. Acute myocardial infarction with pump failure.

D. **Treatment**

1. **Correct hypoxia.** Administer supplemental oxygen as indicated based on arterial pO_2 . Intubation and assisted ventilation may be required.
 - a. If carbon monoxide poisoning is suspected, give 100% oxygen and consider hyperbaric oxygen (see p 482).
 - b. See also treatment guides for cyanide (p 177), hydrogen sulfide (p 224), and methemoglobinemia (p 261).
2. **Treat pneumonia.** Obtain frequent sputum samples and initiate appropriate antibiotic therapy when there is evidence of infection.
 - a. There is no basis for prophylactic antibiotic treatment of aspiration- or chemical-induced pneumonia.
 - b. Although some physicians recommend corticosteroids for chemical-induced pneumonia, there is little evidence of their benefit.
3. **Treat pulmonary edema.**
 - a. Avoid excessive fluid administration. Pulmonary artery cannulation and wedge pressure measurements may be necessary to guide fluid therapy.
 - b. Administer supplemental oxygen to maintain a pO_2 of at least 60–70 mm Hg. Endotracheal intubation and use of positive end-expiratory pressure (PEEP) ventilation may be necessary to maintain adequate oxygenation.

III. **Bronchospasm**

- A. **Assessment.** Examples of drugs and toxins that cause bronchospasm are listed in Table I–3. Bronchospasm may result from the following:

TABLE I-3. SELECTED DRUGS AND TOXINS CAUSING BRONCHOSPASM

Beta blockers	Organophosphates and other anticholinesterases
Chlorine and other irritant gases	Particulate dusts
Drugs causing allergic reactions	Smoke inhalation
Hydrocarbon aspiration	Sulfites (eg, in foods)
Isocyanates	

1. **Direct irritant injury** from inhaled gases or pulmonary aspiration of petroleum distillates or stomach contents.
2. **Pharmacologic effects** of toxins, eg, organophosphate or carbamate insecticides or beta-adrenergic blockers.
3. **Hypersensitivity** or allergic reactions.
- B. Complications.** Severe bronchospasm may result in hypoxia and ventilatory failure.
- C. Differential diagnosis.** Rule out the following:
 1. Asthma or other preexisting bronchospastic disorders.
 2. Stridor caused by upper-airway injury and edema (progressive airway edema may result in acute airway obstruction).
 3. Airway obstruction by a foreign body.
- D. Treatment**
 1. Administer supplemental oxygen. Assist ventilation and perform endotracheal intubation if needed.
 2. Remove the patient from the source of exposure to any irritant gas or other offending agent.
 3. Immediately discontinue any beta-blocker treatment.
 4. Administer bronchodilators:
 - a. Aerosolized beta-2 stimulant (eg, albuterol [2.5–5 mg] in nebulizer). Repeat as needed, or give 5–15 mg as a continuous nebulizer treatment over 1 hour (children: 0.3–0.5 mg/kg/h).
 - b. Aerosolized ipratropium bromide, 0.5 mg every 4–6 hours, especially if excessive cholinergic stimulation is suspected.
 - c. For beta-blocker-induced wheezing, also consider aminophylline (6 mg/kg IV over 30 minutes).
 5. For patients with bronchospasm and bronchorrhea caused by organophosphorus or other cholinesterase inhibitor poisoning, give atropine (see p 412) intravenously. Ipratropium bromide (see 4.b) may also be helpful.

Epstein SK: Decision to extubate. *Intens Care Med* 2002;28(5):535–546. [PMID: 12029399]
(Risk factors for failed extubation include advanced age, longer duration of intubation, and use of continuous intravenous sedation.)

CIRCULATION

I. General assessment and initial treatment

- A. Check blood pressure and pulse rate and rhythm.** Perform cardiopulmonary resuscitation (CPR) if there is no pulse and perform advanced cardiac life support (ACLS) for arrhythmias and shock. Note that some ACLS drugs may be ineffective or dangerous in patients with drug- or poison-induced cardiac disorders. For example, procainamide is contraindicated in patients with tricyclic antidepressant overdose, and atropine and isoproterenol are ineffective in patients with beta-blocker poisoning.
- B. Begin continuous electrocardiographic (ECG) monitoring.** Arrhythmias may complicate a variety of drug overdoses, and all patients with potentially cardiotoxic drug poisoning should be monitored in the emergency department or an intensive care unit for at least 6 hours after the ingestion.

- C. Secure venous access.** Antecubital or forearm veins are usually easy to cannulate. Alternative sites include femoral, subclavian, internal jugular, or other central veins. Access to central veins is technically more difficult but allows measurement of central venous pressure and placement of a pacemaker or pulmonary artery lines.
- D. Draw blood** for routine studies (see p 31).
- E. Begin intravenous infusion** of normal saline (NS), 5% dextrose in NS (D5-NS), 5% dextrose in half NS (D5W 0.45% sodium chloride), or 5% dextrose in water (D5W) at a keep-open rate; for children, use 5% dextrose in quarter NS (D5W 0.25% sodium chloride). If the patient is hypotensive (see p 16), NS or another isotonic crystalloid solution is preferred.
- F.** In seriously ill patients (eg, those who are hypotensive, obtunded, convulsing, or comatose), **place a Foley catheter** in the bladder, obtain urine for routine and toxicologic testing, and measure hourly urine output.
- II. Bradycardia and atrioventricular (AV) block**
- A. Assessment.** Examples of drugs and toxins causing bradycardia or AV block and their mechanisms are listed in Table I-4.
1. Bradycardia and AV block are common features of intoxication with calcium antagonists (see p 144) and drugs that depress sympathetic tone or increase parasympathetic tone. These conditions may also result from severe intoxication with membrane-depressant drugs (eg, tricyclic antidepressants, quinidine, or other type Ia and Ic antiarrhythmic agents).
 2. Bradycardia or AV block may also be a reflex response (baroreceptor reflex) to hypertension induced by alpha-adrenergic agents such as phenylpropanolamine or phenylephrine.
 3. In children, bradycardia is commonly caused by respiratory compromise and usually responds to ventilation and oxygenation.
- B. Complications.** Bradycardia and AV block frequently cause hypotension, which may progress to asystolic cardiac arrest.
- C. Differential diagnosis.** Rule out the following:
1. Hypothermia.
 2. Myocardial ischemia or infarction.
 3. Electrolyte abnormality (eg, hyperkalemia).
 4. Metabolic disturbance (eg, hypothyroidism).
 5. Physiologic origin, due to an intrinsically slow pulse rate (common in athletes) or an acute vaso-vagal reaction.
 6. Cushing reflex (caused by severe intracranial hypertension).
- D. Treatment.** Do **not** treat bradycardia or AV block unless the patient is symptomatic (eg, exhibits signs of syncope or hypotension). **Note:** Bradycardia or even AV block may be a protective reflex to lower the blood pressure in a patient with life-threatening hypertension (see item VII below).

TABLE I-4. SELECTED DRUGS AND TOXINS CAUSING BRADYCARDIA OR ATRIOVENTRICULAR BLOCK^a

Cholinergic or vagotonic agents	Sympatholytic agents
Digitalis glycosides	Beta blockers
Organophosphates and carbamates	Clonidine
Physostigmine, neostigmine	Opiates
Membrane-depressant drugs	Other
Propranolol and other beta blockers	Calcium antagonists
Encainide and flecainide	Carbamazepine
Quinidine, procainamide, and disopyramide	Lithium
Tricyclic antidepressants	Phenylpropanolamine and other alpha-adrenergic agonists
	Propoxyphene

^aAdapted in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:71.

1. Maintain an open airway and assist ventilation (see pp 1–7) if necessary. Administer supplemental oxygen.
2. Rewarm hypothermic patients. A sinus bradycardia of 40–50/min is normal when the body temperature is 32–35°C (90–95°F).
3. Administer atropine, 0.01–0.03 mg/kg IV (see p 412). If this is not successful, use isoproterenol 1–10 mcg/min IV (see p 458), titrated to the desired rate, or use an emergency transcutaneous or transvenous pacemaker.
4. Use the following specific antidotes if appropriate:
 - a. For beta-blocker overdose, give glucagon (see p 449).
 - b. For digitalis intoxication, use Fab fragments (see p 434).
 - c. For tricyclic antidepressant or membrane-depressant drug overdose, administer sodium bicarbonate (see p 419).
 - d. For calcium antagonist overdose, give calcium (see p 424).

III. QRS interval prolongation

A. Assessment. Examples of drugs and toxins causing QRS interval prolongation are listed in Table I–5.

1. QRS interval prolongation of greater than 0.12 seconds in the limb leads (Figure I–4) strongly indicates serious poisoning by tricyclic antidepressants (see p 90) or other membrane-depressant drugs (eg, quinidine [p 324], flecainide [p 78], chloroquine [p 165], and propranolol [p 131]).
2. QRS interval prolongation may also result from a ventricular escape rhythm in a patient with complete heart block (eg, from digitalis, calcium antagonist poisoning, or intrinsic cardiac disease).

B. Complications. QRS interval prolongation in patients with tricyclic antidepressant or similar drug poisonings is often accompanied by hypotension, AV block, and seizures.

C. Differential diagnosis. Rule out the following:

1. Intrinsic conduction system disease (bundle branch block or complete heart block) caused by coronary artery disease. Check an old ECG if available.
2. Hyperkalemia with critical cardiac toxicity may appear as a “sine wave” pattern with markedly wide QRS complexes. These are usually preceded by peaked T waves (Figure I–5).
3. Hypothermia with a core temperature of less than 32°C (90°F) often causes an extra terminal QRS deflection (J wave or Osborne wave), resulting in a widened QRS appearance (Figure I–6).

D. Treatment

1. Maintain the airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat hyperkalemia (see p 37) and hypothermia (p 20) if they occur.
3. Treat AV block with atropine (see p 412), isoproterenol (p 458), and a pacemaker if necessary.
4. For tricyclic antidepressant or other sodium channel-blocking drug overdose, give sodium bicarbonate, 1–2 mEq/kg IV bolus (see p 419); repeat as needed.
5. Give other antidotes if appropriate:

TABLE I–5. SELECTED DRUGS AND TOXINS CAUSING QRS INTERVAL PROLONGATION^a

Beta blockers (propranolol)	Hyperkalemia
Chloroquine and related agents	Phenothiazines (thioridazine)
Digitalis glycosides (complete heart block)	Propoxyphene
Diphenhydramine	Quinidine, procainamide, and disopyramide
Encainide and flecainide	Tricyclic antidepressants

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:71.

FIGURE I-4. Widened QRS interval caused by tricyclic antidepressant overdose. A: Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). B and C: Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Modified and reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: *Clinical Management of Poisoning and Drug Overdose*, Haddad LM, Winchester JF [editors]. Philadelphia: WB Saunders, 1983, p 71.)

- a. Digoxin-specific Fab antibodies for complete heart block induced by digitalis (see p 434).
- b. Glucagon for beta-blocker intoxication (see p 449).
- c. Calcium for calcium antagonist poisoning (see p 424).

IV. Tachycardia

A. Assessment. Examples of drugs and toxins causing tachycardia and their mechanisms are shown in Table I-6.

1. Sinus tachycardia and supraventricular tachycardia are often caused by excessive sympathetic system stimulation or inhibition of parasympathetic tone. Sinus tachycardia may also be a reflex response to hypotension or hypoxia.
2. Sinus tachycardia and supraventricular tachycardia accompanied by QRS interval prolongation (eg, with tricyclic antidepressant poisoning) may have the appearance of ventricular tachycardia (see Figure I-4).

FIGURE I-5. Electrocardiogram of patient with hyperkalemia. (Modified and reproduced, with permission, from Goldschlager N, Goldman MJ: Effect of drugs and electrolytes on the electrocardiogram. In: *Electrocardiography: Essentials of Interpretation*. Goldschlager N, Goldman MJ [editors]. New York: Lange, 1984, p 199.)

FIGURE I-6. Electrocardiogram of patient with hypothermia, showing prominent J waves. (Modified and reproduced, with permission, from Goldschlager N, Goldman MJ: Miscellaneous abnormal electrocardiogram patterns. In: *Electrocardiography: Essentials of Interpretation*. Goldschlager N, Goldman MJ [editors]. New York: Lange, 1984, p 227.)

- B. Complications.** Simple sinus tachycardia (heart rate < 140/min) is rarely of hemodynamic consequence; children and healthy adults easily tolerate rates up to 160–180/min. However, sustained rapid rates may result in hypotension, chest pain, or syncope.
- C. Differential diagnosis.** Rule out the following:
1. Occult blood loss (eg, from gastrointestinal bleeding, or trauma).
 2. Fluid loss (eg, from gastritis or gastroenteritis).
 3. Hypoxia.
 4. Fever and infection.
 5. Myocardial infarction.
 6. Anxiety.
 7. Intrinsic conduction system disease (eg, Wolff-Parkinson-White syndrome).
- D. Treatment.** If tachycardia is not associated with hypotension or chest pain, observation and sedation (especially for stimulant intoxication) are usually adequate.
1. For sympathomimetic-induced tachycardia, give propranolol, 0.01–0.03 mg/kg IV (see p 496); or esmolol, 0.025–0.1 mg/kg/min IV (p 443).
 2. For anticholinergic-induced tachycardia, give physostigmine, 0.01–0.03 mg/kg IV (see p 489); or neostigmine, 0.01–0.03 mg/kg IV. **Caution:** Do not use these drugs in patients with tricyclic antidepressant overdose, because additive depression of conduction may result in asystole.
- V. Ventricular arrhythmias**
- A. Assessment.** Examples of drugs and toxins causing ventricular arrhythmias are listed in Table I-7.
1. Ventricular irritability is commonly associated with excessive sympathetic stimulation (eg, from cocaine or amphetamines). Patients intoxicated by

TABLE I-6. SELECTED DRUGS AND TOXINS CAUSING TACHYCARDIA^a

Sympathomimetic agents	Anticholinergic agents
Amphetamines and derivatives	<i>Amanita muscaria</i> mushrooms
Caffeine	Antihistamines
Cocaine	Atropine and other anticholinergics
Ephedrine and pseudoephedrine	Phenothiazines
Phencyclidine (PCP)	Plants (many: see p 309)
Theophylline	Tricyclic antidepressants
Agents causing cellular hypoxia	Other
Carbon monoxide	Ethanol or sedative-hypnotic drug withdrawal
Cyanide	Vasodilators (reflex tachycardia)
Hydrogen sulfide	Thyroid hormone
Oxidizing agents (methemoglobinemia)	

^aAdapted, with permission, from Olson KR et al: *Med Toxicol* 1987;2:71.

TABLE I-7. SELECTED DRUGS AND TOXINS CAUSING VENTRICULAR ARRHYTHMIAS^a**Ventricular tachycardia or fibrillation**

Amphetamines and other sympathomimetic agents	Digitalis glycosides
Aromatic hydrocarbon solvents	Fluoride
Caffeine	Phenothiazines
Chloral hydrate	Theophylline
Chlorinated or fluorinated hydrocarbon solvents	Tricyclic antidepressants
Cocaine	

QT prolongation or torsade de pointes^b

Amiodarone	Moexipril
Arsenic	Moxifloxacin
Astemizole and terfenadine	Naratriptan
Bepiridil	Nicardipine
Chloroquine, quinine, and related agents	Octreotide
Cisapride	Organophosphate insecticides
Citrate	Paroxetine
Clarithromycin	Pentamidine
Dofetilide	Pimozide
Dolasetron	Quetiapine
Droperidol and haloperidol	Quinidine, procainamide, and disopyramide
Erythromycin	Risperidone
Felbamate	Salmeterol
Flecainide	Sertraline
Fluoride	Sotalol
Fluoxetine	Sparfloxacin
Foscarnet	Sumatriptan
Fosphenytoin	Tacrolimus
Gatifloxacin	Tamoxifen
Halofantrine	Thallium
Ibutilide	Thioridazine
Indapamide	Tizanidine
Isradipine	Tricyclic antidepressants
Levofloxacin	Venlafaxine
Levomethadyl	Ziprasidone
Mesoridazine	Zolmitriptan

^aReferences: Olson KR et al: *Med Toxicol* 1987;2:71; and Woolsey RL: Drugs that prolong the QT interval and/or induce torsades de pointes. Internet: <http://www.torsades.org>

^bTorsade de pointes can deteriorate into ventricular fibrillation and cardiac arrest.

chlorinated, fluorinated, or aromatic hydrocarbons may have heightened myocardial sensitivity to the arrhythmogenic effects of catecholamines.

2. Ventricular tachycardia may also be a manifestation of intoxication by a tricyclic antidepressant or other sodium channel-blocking drug, although with these drugs true ventricular tachycardia may be difficult to distinguish from sinus or supraventricular tachycardia accompanied by QRS interval prolongation (see Figure I-4).
 3. Agents that cause **QT interval prolongation** (QTc > 0.42 seconds) may produce "atypical" ventricular tachycardia (torsade de pointes). **Torsade de pointes** is characterized by polymorphous ventricular tachycardia that appears to rotate its axis continuously (Figure I-7). Torsade de pointes may also be caused by hypokalemia, hypocalcemia, or hypomagnesemia.
- B. Complications.** Ventricular tachycardia in patients with a pulse may be associated with hypotension or may deteriorate into pulseless ventricular tachycardia or ventricular fibrillation.
- C. Differential diagnosis.** Rule out the following possible causes of ventricular premature beats, ventricular tachycardia, or ventricular fibrillation:
1. Hypoxemia.

FIGURE I-7. Polymorphic ventricular tachycardia (torsade de pointes). (Modified and reproduced, with permission, from Goldschlager N, Goldman MJ: Effect of drugs and electrolytes on the electrocardiogram. In: *Electrocardiography: Essentials of Interpretation*. Goldschlager N, Goldman MJ [editors]. New York: Lange, 1984, p 197.)

2. Hypokalemia.
3. Metabolic acidosis.
4. Myocardial ischemia or infarction.
5. Electrolyte disturbances (eg, hypocalcemia or hypomagnesemia) or congenital disorders that may cause QT prolongation and torsade de pointes.
- D. Treatment.** Perform CPR if necessary, and follow standard guidelines for management of arrhythmias, with the exception that procainamide and bretylium should **not** be used, especially if tricyclic antidepressant or sodium channel-blocking drug overdose is suspected.
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Correct acid-base and electrolyte disturbances.
 3. **For ventricular fibrillation**, immediately apply direct-current countershock at 3–5 J/kg. Repeat twice if no response. Continue CPR if the patient is still without a pulse, and administer epinephrine, repeated countershocks, amiodarone, and/or lidocaine as recommended in advanced cardiac life support (ACLS) guidelines.
 4. **For ventricular tachycardia in patients without a pulse**, immediately give a precordial thump or apply synchronized direct-current countershock at 1–3 J/kg. If this is not successful, begin CPR and apply countershock at 3–5 J/kg; administer amiodarone and/or lidocaine and repeated countershocks as recommended in ACLS guidelines.
 5. **For ventricular tachycardia in patients with a pulse**, use lidocaine, 1–3 mg/kg IV (see p 462), or amiodarone, 300 mg IV or 5 mg/kg in children. Do **not** use procainamide (Pronestyl) or other type Ia antiarrhythmic agents. For suspected myocardial sensitivity caused by chloral hydrate or halogenated or aromatic hydrocarbons, use esmolol, 0.025–0.100 mg/kg/min IV (see p 443), or propranolol, 0.5–3 mg IV (p 496).
 6. **For tricyclic antidepressant or other sodium channel-blocking drug overdose**, administer sodium bicarbonate, 1–2 mEq/kg IV (see p 419), in repeated boluses until the QRS interval narrows or the serum pH exceeds 7.7.
 7. **For “atypical” or polymorphic ventricular tachycardia (torsade de pointes)**, do the following:
 - a. Use overdrive pacing or isoproterenol, 1–10 mcg/min IV (see p 458), to increase the heart rate (this makes repolarization more homogeneous and abolishes the arrhythmia).
 - b. Alternately, administer intravenous magnesium sulfate, 1–2 g in adults, over 20–30 minutes (see p 463).

VI. Hypotension

- A. Assessment.** Examples of drugs and toxins causing hypotension and their mechanisms are listed in Table I-8.
1. Physiologic derangements resulting in hypotension include volume loss because of vomiting, diarrhea, or bleeding; apparent volume depletion caused by venodilation; arteriolar dilation; depression of cardiac contractility; arrhythmias that interfere with cardiac output; and hypothermia.
 2. Volume loss, venodilation, and arteriolar dilation are likely to result in hypotension with reflex tachycardia. In contrast, hypotension accompanied by bradycardia should suggest intoxication by sympatholytic agents, membrane-depressant drugs, calcium channel blockers, or cardiac glycosides or the presence of hypothermia.
- B. Complications.** Severe or prolonged hypotension can cause acute renal tubular necrosis, brain damage, and cardiac ischemia. Metabolic acidosis is a common finding.
- C. Differential diagnosis.** Rule out the following:
1. Hypothermia, which results in a decreased metabolic rate and lowered blood pressure demands.
 2. Hyperthermia, which causes arteriolar dilation and venodilation and direct myocardial depression.
 3. Fluid loss caused by gastroenteritis.
 4. Blood loss (eg, from trauma or gastrointestinal bleeding).
 5. Myocardial infarction.
 6. Sepsis.
 7. Spinal cord injury.
- D. Treatment.** Fortunately, hypotension usually responds readily to empirical therapy with intravenous fluids and low doses of pressor drugs (eg, dopamine). When hypotension does not resolve after simple measures, a systematic approach should be followed to determine the cause of hypotension and to select the appropriate treatment.

TABLE I-8. SELECTED DRUGS AND TOXINS CAUSING HYPOTENSION^a

HYPOTENSION WITH RELATIVE BRADYCARDIA	HYPOTENSION WITH TACHYCARDIA
Sympatholytic agents Beta blockers Bretylium Clonidine and methyldopa Hypothermia Opiates Reserpine Tetrahydrozoline and oxymetazoline	Fluid loss or third spacing Amatoxin-containing mushrooms Arsenic Colchicine Copper sulfate Hyperthermia Iron Rattlesnake envenomation Sedative-hypnotic agents
Membrane-depressant drugs Beta blockers (mainly propranolol) Encainide and flecainide Quinidine, procainamide, and disopyramide Propoxyphene Tricyclic antidepressants	Peripheral venous or arteriolar dilation Alpha antagonists (doxazosin, prazosin, terazosin) Beta-2 stimulants (eg, albuterol) Caffeine Calcium antagonists (nifedipine, amlodipine, nicardipine) Hydralazine Hyperthermia Minoxidil Nitrites Nitroprusside Phenothiazines Theophylline Tricyclic antidepressants
Others Barbiturates Calcium antagonists (verapamil, diltiazem) Fluoride Organophosphates and carbamates Sedative-hypnotic agents	

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:57.

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat cardiac arrhythmias that may contribute to hypotension (heart rate < 40–50/min or > 180–200/min [see pp 10–13]).
3. Hypotension associated with hypothermia often will not improve with routine fluid therapy but will rapidly normalize upon rewarming of the patient. A systolic blood pressure of 80–90 mm Hg is expected when the body temperature is 32°C (90°F).
4. Give a fluid challenge using NS, 10–20 mL/kg, or another crystalloid solution.
5. Administer dopamine, 5–15 mcg/kg/min (see p 438). Note that dopamine may be ineffective in some patients with depleted neuronal stores of catecholamines (eg, from disulfiram [p 186], reserpine, or tricyclic antidepressant [p 90] overdose). In such cases norepinephrine, 0.1 mcg/kg/min IV (p 479), may be more effective.
6. Consider specific antidotes:
 - a. Sodium bicarbonate (see p 419) for tricyclic antidepressant or other sodium channel-blocking drug overdose.
 - b. Glucagon (see p 449) for beta-blocker overdose.
 - c. Calcium (see p 424) for calcium antagonist overdose.
 - d. Propranolol (see p 496) or esmolol (p 443) for theophylline, caffeine, or metaproterenol or other beta-agonist overdose.
7. If the above measures are unsuccessful, insert a central venous pressure (CVP) monitor or pulmonary artery catheter to determine whether further fluids are needed and to measure the cardiac output (CO) and calculate the systemic vascular resistance (SVR) as follows:

$$\text{SVR} = \frac{80(\text{MAP} - \text{CVP})}{\text{CO}}$$

where MAP is the mean arterial pressure and normal SVR = 770–1500. Select further therapy based on the following results:

- a. If the central venous pressure or pulmonary artery wedge pressure remains low, give more intravenous fluids.
- b. If the cardiac output is low, give more dopamine (see p 438) or dobutamine.
- c. If the systemic vascular resistance is low, administer norepinephrine, 4–8 mcg/min (see p 479).

VII. Hypertension

A. Assessment. Hypertension is frequently overlooked in drug-intoxicated patients and often goes untreated. Many young persons have normal blood pressures in the range of 90/60 mm Hg to 100/70 mm Hg; in such a person an abrupt elevation to 170/100 is much more significant (and potentially catastrophic) than the same blood pressure elevation in an older person with chronic hypertension. Examples of drugs and toxins causing hypertension are listed in Table I–9. Hypertension may be caused by a variety of mechanisms:

1. Amphetamines and other related drugs cause hypertension and tachycardia through generalized sympathetic stimulation.
2. Selective alpha-adrenergic agents cause hypertension with reflex (baroreceptor-mediated) bradycardia or even AV block.
3. Anticholinergic agents cause mild hypertension with tachycardia.
4. Substances that stimulate nicotinic cholinergic receptors (eg, organophosphates) may initially cause tachycardia and hypertension, followed later by bradycardia and hypotension.

B. Complications. Severe hypertension can result in intracranial hemorrhage, aortic dissection, myocardial infarction, and congestive heart failure.

TABLE I-9. SELECTED DRUGS AND TOXINS CAUSING HYPERTENSION^a**HYPERTENSION WITH TACHYCARDIA****Generalized sympathomimetic agents**

Amphetamines and derivatives
Cocaine
Ephedrine and pseudoephedrine
Epinephrine
Levodopa
LSD (lysergic acid diethylamide)
Marihuana
Monoamine oxidase inhibitors

Anticholinergic agents^b

Antihistamines
Atropine and other anticholinergics
Tricyclic antidepressants

Other

Ethanol and sedative-hypnotic drug withdrawal
Nicotine (early stage)
Organophosphates (early stage)

HYPERTENSION WITH BRADYCARDIA OR ATRIOVENTRICULAR BLOCK

Clonidine, tetrahydrozoline, and oxymetazoline^c
Ergot derivatives
Methoxamine

Norepinephrine
Phenylephrine
Phenylpropanolamine

^aAdapted, in part, with permission, from Olson KR et al. *Med Toxicol* 1987;2:56.

^bHypertension usually mild and associated with therapeutic or slightly supratherapeutic levels. Overdose may cause hypotension, especially with tricyclics.

^cHypertension often transient and followed by hypotension.

C. Differential diagnosis. Rule out the following:

1. Idiopathic hypertension (which is common in the general population). However, without a prior history of hypertension, it should not be initially assumed to be the cause of the elevated blood pressure.
2. Increased intracranial pressure caused by spontaneous hemorrhage, trauma, or other causes. This may result in hypertension with reflex bradycardia (Cushing reflex).

D. Treatment. Rapid lowering of the blood pressure is desirable as long as it does not result in hypotension, which can potentially cause an ischemic cerebral infarction in older patients with cerebrovascular disease. For a patient with chronic hypertension, lowering the diastolic pressure to 100 mm Hg is acceptable. On the other hand, for a young person whose normal diastolic blood pressure is 60 mm Hg, the diastolic pressure should be lowered to 80 mm Hg.

1. **For hypertension with little or no tachycardia**, use phentolamine, 0.02–0.1 mg/kg IV (see p 487), or nitroprusside, 2–10 mcg/kg/min IV (p 477).
2. **For hypertension with tachycardia**, add to the treatment in item 1 above propranolol, 0.02–0.1 mg/kg IV (p 496); or esmolol, 0.025–0.1 mg/kg/min IV (p 443); or labetalol, 0.2–0.3 mg/kg IV (p 459). **Caution:** Do not use propranolol or esmolol alone to treat hypertensive crisis; beta-blockers may paradoxically worsen hypertension if it is caused primarily by alpha-adrenergic stimulation.
3. **If hypertension is accompanied by a focally abnormal neurologic examination** (eg, hemiparesis), perform a computed tomography (CT) scan as quickly as possible. In a patient with a cerebrovascular accident, hypertension should generally not be treated unless specific complications of the elevated pressure (eg, heart failure or cardiac ischemia) are present. Consult a neurologist.

Khan IA: Clinical and therapeutic aspects of congenital and acquired long QT syndrome. *Am J Med* 2002;112(1):58–66. [PMID: 11812408] (Review of causes of prolonged QT interval and management of torsade de pointes.)

ALTERED MENTAL STATUS

I. Coma and stupor

A. Assessment. A decreased level of consciousness is the most common serious complication of drug overdose or poisoning. Examples of drugs and toxins causing coma are listed in Table I–10.

1. Coma is most often a result of global depression of the brain's reticular activating system, caused by anticholinergic agents, sympatholytic drugs, generalized CNS depressants, or toxins that result in cellular hypoxia.
2. Coma sometimes represents a postictal phenomenon after a drug- or toxin-induced seizure.
3. Coma may also be caused by brain injury associated with infarction or intracranial bleeding. Brain injury is suggested by the presence of focal neurologic deficits and is confirmed by a CT scan.

B. Complications. Coma is frequently accompanied by respiratory depression, which is a major cause of death. Other conditions that may accompany or complicate coma include hypotension (see p 16), hypothermia (p 20), hyperthermia (p 21), and rhabdomyolysis (p 27).

C. Differential diagnosis. Rule out the following:

1. Head trauma or other causes of intracranial bleeding.
2. Abnormal levels of blood glucose, sodium, or other electrolytes.
3. Hypoxia.
4. Hypothyroidism.
5. Liver or renal failure.
6. Environmental hyperthermia or hypothermia.
7. Serious infections such as encephalitis or meningitis.

D. Treatment

1. Maintain the airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Give dextrose, thiamine, and naloxone.

a. Dextrose. All patients with depressed consciousness should receive concentrated dextrose unless hypoglycemia is ruled out with an immediate bedside glucose determination. Use a secure vein and avoid extravasation; concentrated dextrose is highly irritating to tissues. Initial doses include the following:

TABLE I–10. SELECTED DRUGS AND TOXINS CAUSING COMA OR STUPOR^a

Generalized CNS depressants	Cellular hypoxia
Anticholinergics	Carbon monoxide
Antihistamines	Cyanide
Barbiturates	Hydrogen sulfide
Benzodiazepines	Methemoglobinemia
Carbamazepine	Sodium azide
Ethanol and other alcohols	Other or unknown mechanisms
GHB (gamma hydroxybutyrate)	Bromide
Phenothiazines	Diquat
Sedative-hypnotic agents	Disulfiram
Tricyclic antidepressants	Hypoglycemic agents
Valproic acid	Lithium
Sympatholytic agents	Phencyclidine
Clonidine, tetrahydrozoline, and oxymetazoline	Phenylbutazone and enolic acid derivatives
Methylidopa	Salicylates
Opiates	

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:61.

- (1) Adults: 50% dextrose, 50 mL (25 g) IV.
- (2) Children: 25% dextrose, 2 mL/kg IV.
- b. **Thiamine.** Thiamine is given to prevent abrupt precipitation of Wernicke's syndrome resulting from thiamine deficiency in alcoholic patients and others with suspected vitamin deficiencies. It is not given routinely to children. Give thiamine, 100 mg, in the IV bottle or intramuscularly (see p 505).
- c. **Naloxone.** All patients with respiratory depression should receive naloxone (see p 469); if a patient is already intubated and being artificially ventilated, then naloxone is not immediately necessary and can be considered a diagnostic rather than therapeutic drug. **Caution:** Although naloxone has no CNS depressant activity of its own and can normally be given safely in large doses, it may precipitate abrupt opiate withdrawal. If an amphetamine or cocaine has been injected along with heroin, reversal of the opiate-induced sedation may unmask stimulant-mediated hypertension, tachycardia, or psychosis. In addition, acute pulmonary edema is sometimes temporally associated with abrupt naloxone reversal of opiate intoxication.
 - (1) Give naloxone, 0.4 mg IV (may also be given intramuscularly [IM]).
 - (2) If there is no response within 1–2 minutes, give naloxone, 2 mg IV.
 - (3) If there is still no response and opiate overdose is highly suspected by history or clinical presentation (pinpoint pupils, apnea, or hypotension), give naloxone, 10–20 mg IV.
- d. Consider **flumazenil** if benzodiazepines are the only suspected cause of coma and there are no contraindications (see p 446). **Caution:** Use of flumazenil can precipitate seizures in patients who are addicted to benzodiazepines or who have co-ingested a convulsant drug or poison.
3. Normalize the body temperature (see hypothermia, p 20, or hyperthermia, p 21).
4. If there is any possibility of CNS trauma or cerebrovascular accident, perform a CT scan.
5. If meningitis or encephalitis is suspected, perform a lumbar puncture and treat with appropriate antibiotics.

II. Hypothermia

- A. **Assessment.** Hypothermia may mimic or complicate drug overdose and should be suspected in every comatose patient. Examples of drugs and toxins causing hypothermia are listed in Table I-11.
1. Hypothermia is usually caused by exposure to low ambient temperatures in a patient with blunted thermoregulatory response mechanisms. Drugs and toxins may induce hypothermia by causing vasodilation, inhibiting the shivering response, decreasing metabolic activity, or causing loss of consciousness in a cold environment.
2. A patient whose temperature is lower than 32°C (90°F) may appear to be dead, with a barely detectable pulse or blood pressure and without reflexes. The ECG may reveal an abnormal terminal deflection (J wave or Osborne wave; see Figure I-6).

TABLE I-11. SELECTED DRUGS AND TOXINS ASSOCIATED WITH HYPOTHERMIA^a

Barbiturates	Phenothiazines
Ethanol and other alcohols	Sedative-hypnotic agents
Hypoglycemic agents	Tricyclic antidepressants
Opiates	Vasodilators

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:60.

- B. Complications.** Because there is a generalized reduction of metabolic activity and less demand for blood flow, hypothermia is commonly accompanied by hypotension and bradycardia.
1. Mild hypotension (systolic blood pressure of 70–90 mm Hg) in a patient with hypothermia should not be aggressively treated; excessive intravenous fluids may cause fluid overload and further lowering of the temperature.
 2. Severe hypothermia (temperature < 28–30°C) may cause intractable ventricular fibrillation and cardiac arrest. This may occur abruptly, such as when the patient is moved or rewarmed too quickly or when CPR is performed.
- C. Differential diagnosis.** Rule out the following:
1. Sepsis.
 2. Hypoglycemia.
 3. Hypothyroidism.
 4. Environmental hypothermia, caused by exposure to a cold environment.
- D. Treatment**
1. Maintain the airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Because the pulse rate may be profoundly slow (10/min) and weak, perform careful cardiac evaluation before assuming that the patient is in cardiac arrest. Do **not** treat bradycardia; it will resolve with rewarming.
 3. Unless the patient is in cardiac arrest (asystole or ventricular fibrillation), rewarm slowly (using blankets, warm intravenous fluids, and warmed-mist inhalation) to prevent rewarming arrhythmias.
 4. For patients in cardiac arrest, usual antiarrhythmic agents and direct-current countershock are frequently ineffective until the core temperature is above 32–35°C (90–95°F). Provide gastric or peritoneal lavage with warmed fluids and perform CPR. For ventricular fibrillation, bretylium, 5–10 mg/kg IV (see p 421), may be effective.
 5. Open cardiac massage, with direct warm irrigation of the ventricle, or a partial cardiopulmonary bypass may be necessary in hypothermic patients in cardiac arrest who are unresponsive to the above treatment.

III. Hyperthermia

- A. Assessment.** Hyperthermia (temperature > 40°C or 104°F) may be a catastrophic complication of intoxication by a variety of drugs and toxins (Table I–12). It may be caused by excessive heat generation because of sustained seizures, rigidity, or other muscular hyperactivity; an increased metabolic rate; impaired dissipation of heat secondary to impaired sweating (eg, anticholinergic agents); or hypothalamic disorders.

TABLE I–12. SELECTED DRUGS AND TOXINS ASSOCIATED WITH HYPERTHERMIA^a

Excessive muscular hyperactivity, rigidity, or seizures	Impaired heat dissipation or disrupted thermoregulation
Amoxapine	Amoxapine
Amphetamines and derivatives (including MDMA)	Anticholinergic agents
Cocaine	Antihistamines
Lithium	Phenothiazines and other antipsychotic agents
LSD (lysergic acid diethylamide)	Tricyclic antidepressants
Maprotiline	Other
Monoamine oxidase inhibitors	Exertional heatstroke
Phencyclidine	Malignant hyperthermia
Tricyclic antidepressants	Metal fume fever
Increased metabolic rate	Neuroleptic malignant syndrome (NMS)
Dinitrophenol and pentachlorophenol	Serotonin syndrome
Salicylates	Withdrawal from ethanol or sedative-hypnotic drugs
Thyroid hormone	

^aAdapted, with permission, from Olson KR et al: *Med Toxicol* 1987;2:59.

1. **Neuroleptic malignant syndrome (NMS)** is a hyperthermic disorder seen in some patients who use antipsychotic agents and is characterized by hyperthermia, muscle rigidity (often so severe as to be called "lead-pipe" rigidity), metabolic acidosis, and confusion.
2. **Malignant hyperthermia** is an inherited disorder that causes severe hyperthermia, metabolic acidosis, and rigidity after certain anesthetic agents (most commonly halothane and succinylcholine) are used.
3. **Serotonin syndrome** occurs primarily in patients taking monoamine oxidase (MAO) inhibitors (see p 269) who also take serotonin-enhancing drugs, such as meperidine (Demerol™), fluoxetine (Prozac™), or other serotonin reuptake inhibitors (SSRIs; see Antidepressants, p 88), and is characterized by irritability, rigidity, myoclonus, diaphoresis, autonomic instability, and hyperthermia. It may also occur in people taking an overdose of or combinations of SSRIs even without concurrent use of MAO inhibitors.
- B. **Complications.** Untreated, severe hyperthermia is likely to result in hypotension, rhabdomyolysis, coagulopathy, cardiac and renal failure, brain injury, and death. Survivors often have permanent neurologic sequelae.
- C. **Differential diagnosis.** Rule out the following:
 1. Sedative-hypnotic drug or ethanol withdrawal (delirium tremens).
 2. Exertional or environmental heat stroke.
 3. Thyrotoxicosis.
 4. Meningitis or encephalitis.
 5. Other serious infections.
- D. **Treatment. Immediate rapid cooling** is essential to prevent death or serious brain damage.
 1. Maintain the airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Administer glucose-containing intravenous fluids, and give concentrated glucose bolus (pp 19 and 450) if the patient is hypoglycemic.
 3. Rapidly gain control of seizures (see below), agitation (p 24), or muscular rigidity (p 25).
 4. Begin external cooling with tepid (lukewarm) sponging and fanning. This evaporative method is the most efficient method of cooling.
 5. Shivering often occurs with rapid external cooling, and shivering may generate yet more heat. Some physicians recommend chlorpromazine to abolish shivering, but this agent can lower the seizure threshold, inhibit sweating, and cause hypotension. It is preferable to use diazepam, 0.1–0.2 mg/kg IV; lorazepam, 0.05–0.1 mg/kg IV; or midazolam, 0.05–0.1 mg/kg IV or IM (see p 415); or use neuromuscular paralysis (see below).
 6. The most rapidly effective and reliable means of lowering the temperature is by neuromuscular paralysis. Administer a nondepolarizing agent such as pancuronium, 0.1 mg/kg IV (see p 472); or vecuronium, 0.1 mg/kg IV. **Caution:** The patient will stop breathing; be prepared to ventilate and intubate endotracheally.
 7. **Malignant hyperthermia.** If muscle rigidity persists despite administration of neuromuscular blockers, a defect at the muscle cell level (ie, malignant hyperthermia) should be suspected. Give dantrolene, 1–10 mg/kg IV (see p 431).
 8. **Neuroleptic malignant syndrome.** Consider bromocriptine (see p 422).
 9. **Serotonin syndrome.** Anecdotal case reports suggest benefit with cyproheptadine (Periactin™), 4 mg orally (PO) every hour for 3–4 doses (see p 430); or methysergide, 2 mg PO every 6 hours for 3–4 doses.

IV. Seizures

- A. **Assessment.** Seizures are a major cause of morbidity and mortality from drug overdose or poisoning. Seizures may be single and brief or multiple and sustained and may result from a variety of mechanisms (Table I–13).

TABLE I-13. SELECTED DRUGS AND TOXINS CAUSING SEIZURES^a**Adrenergic-sympathomimetic agents**

Amphetamines and derivatives (including MDMA)
 Caffeine
 Cocaine
 Ephedrine
 Phencyclidine
 Phenylpropanolamine
 Theophylline

Antidepressants and antipsychotics

Amoxapine
 Bupropion
 Haloperidol and butyrophenones
 Loxapine, clozapine, and olanzapine
 Phenothiazines
 Tricyclic antidepressants
 Venlafaxine, other newer serotonin reuptake inhibitors (SSRIs)

Others

Antihistamines (diphenhydramine, hydroxyzine)
 Beta blockers (primarily propranolol; not reported for atenolol, metoprolol, pindolol, or practolol)
 Boric acid
 Camphor
 Carbamazepine
 Cellular hypoxia (eg, carbon monoxide, cyanide, hydrogen sulfide)
 Chlorinated hydrocarbons
 Cholinergic agents (carbamates, nicotine, organophosphates)
 Cicutoxin and other plant toxins
 Citrate
 DEET (diethyltoluamide)
 Ethylene glycol
 Fipronil
 Fluoride

GHB (gamma hydroxybutyrate)
 Isoniazid (INH)
 Lead and other heavy metals
 Lidocaine and other local anesthetics
 Lithium
 Mefenamic acid
 Meperidine (normeperidine metabolite)
 Metaldehyde
 Methanol
 Methyl bromide
 Phenols
 Phenylbutazone
 Piroxicam
 Salicylates
 Strychnine (opisthotonos and rigidity)
 Withdrawal from ethanol or sedative-hypnotic drugs

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:63.

1. Generalized seizures usually result in loss of consciousness, often accompanied by tongue biting and fecal and urinary incontinence.
2. Other causes of muscular hyperactivity or rigidity (see p 25) may be mistaken for seizures, especially if the patient is also unconscious.

B. Complications

1. Any seizure can cause airway compromise, resulting in apnea or pulmonary aspiration.
2. Multiple or prolonged seizures may cause severe metabolic acidosis, hyperthermia, rhabdomyolysis, and brain damage.

C. Differential diagnosis. Rule out the following:

1. Any serious metabolic disturbance (eg, hypoglycemia, hyponatremia, hypocalcemia, or hypoxia).
2. Head trauma with intracranial injury.
3. Idiopathic epilepsy.
4. Withdrawal from alcohol or a sedative-hypnotic drug.
5. Exertional or environmental hyperthermia.
6. CNS infection such as meningitis or encephalitis.
7. Febrile seizures in children.

D. Treatment

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Administer naloxone (see pp 20 and 469) if seizures are thought to be caused by hypoxia resulting from narcotic-associated respiratory depression.
3. Check for hypoglycemia and administer dextrose and thiamine as for coma (see p 19).

4. Use one or more of the following anticonvulsants. **Caution:** Anticonvulsants can cause hypotension, cardiac arrest, or respiratory arrest if administered too rapidly.
 - a. Diazepam, 0.1–0.2 mg/kg IV (see p 415).
 - b. Lorazepam, 0.05–0.1 mg/kg IV (see p 415).
 - c. Midazolam, 0.1–0.2 mg/kg IM (useful when intravenous access is difficult), or 0.05–0.1 mg/kg IV (see p 415).
 - d. Phenobarbital, 10–15 mg/kg IV; slow infusion over 15–20 minutes (see p 486).
 - e. Pentobarbital, 5–6 mg/kg IV; slow infusion over 8–10 minutes, then continuous infusion at 0.5–3 mg/kg/h titrated to effect (p 485).
 - f. Propofol, 2–2.5 mg/kg (children: 2.5–3.5 mg/kg), given in increments (40 mg at a time in adults) IV every 10–20 seconds until desired effect (see p 494).
 - g. Phenytoin, 15–20 mg/kg IV; slow infusion over 25–30 minutes (see p 488). **Note:** Phenytoin is ineffective for convulsions caused by theophylline and is considered the anticonvulsant of last choice for most drug-induced seizures.
5. Immediately check the rectal or tympanic **temperature** and cool the patient rapidly (see p 22) if the temperature is above 40°C (104°F). The most rapid and reliably effective method of temperature control is neuromuscular paralysis with pancuronium, 0.1 mg/kg IV (p 472) or another nondepolarizing neuromuscular blocker. **Caution:** If paralysis is used, the patient must be intubated and ventilated; in addition, monitor the electroencephalogram (EEG) for continued brain seizure activity because peripheral muscular hyperactivity is no longer visible.
6. Use the following specific antidotes if available:
 - a. Pyridoxine (see p 499) for isoniazid (INH; p 233).
 - b. Pralidoxime (2-PAM; see p 492) or atropine (p 412), or both, for organophosphate or carbamate insecticides (p 291).

V. Agitation, delirium, or psychosis

- A. **Assessment.** Agitation, delirium, or psychosis may be caused by a variety of drugs and toxins (Table I–14). In addition, such symptoms may result from a functional thought disorder or metabolic encephalopathy caused by medical illness.
 1. Functional psychosis or stimulant-induced agitation and psychosis are usually associated with an intact sensorium, and hallucinations are predominantly auditory.

TABLE I–14. SELECTED DRUGS AND TOXINS CAUSING AGITATION, DELIRIUM, OR CONFUSION^a

Predominant confusion or delirium	Predominant agitation or psychosis
Amantadine	Amphetamines and derivatives
Anticholinergic agents	Caffeine
Antihistamines	Cocaine
Bromide	Cycloserine
Carbon monoxide	Dextromethorphan
Cimetidine and other H-2 blockers	LSD (lysergic acid diethylamide)
Disulfiram	Marihuana
Lead and other heavy metals	Mercury
Levodopa	Phencyclidine (PCP)
Lidocaine and other local anesthetics	Procaine
Lithium	Serotonin reuptake inhibitors (SSRIs)
Salicylates	Steroids (eg, prednisone)
Withdrawal from ethanol or sedative-hypnotic drugs	Theophylline

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:62.

2. With metabolic encephalopathy or drug-induced delirium, there is usually alteration of the sensorium (manifested by confusion or disorientation). Hallucinations, when they occur, are predominantly visual.
- B. Complications.** Agitation, especially if accompanied by hyperkinetic behavior and struggling, may result in hyperthermia (see p 21) and rhabdomyolysis (p 27).
- C. Differential diagnosis.** Rule out the following:
 1. Serious metabolic disturbance (hypoxia, hypoglycemia, or hyponatremia).
 2. Alcohol or sedative-hypnotic drug withdrawal.
 3. Thyrotoxicosis.
 4. CNS infection such as meningitis or encephalitis.
 5. Exertion-induced or environmental hyperthermia.
- D. Treatment.** Sometimes the patient can be calmed with reassuring words and reduction of noise, light, and physical stimulation. If this is not quickly effective, rapidly gain control of the patient to determine the rectal or tympanic temperature and begin rapid cooling and other treatment if needed.
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Treat hypoglycemia (see p 34), hypoxia (p 7), or other metabolic disturbances.
 3. Administer one of the following sedatives:
 - a. Midazolam, 0.05–0.1 mg/kg IV over 1 minute, or 0.1–0.2 mg/kg IM (see p 415).
 - b. Lorazepam, 0.05–0.1 mg/kg IV over 1 minute (see p 415).
 - c. Diazepam, 0.1–0.2 mg/kg IV over 1 minute (see p 415).
 - d. Droperidol, 2.5–5 mg IV; or haloperidol, 0.1–0.2 mg/kg IM or IV over 1 minute (see p 451). **Note:** Do not give haloperidol decanoate salt intravenously. **Caution:** Both droperidol and haloperidol have caused prolongation of the QT interval and polymorphic ventricular tachycardia (torsade de pointes), and should be avoided in patients with preexisting QT prolongation or with toxicity from agents known to prolong the QT.
 4. If hyperthermia occurs as a result of excessive muscular hyperactivity, then skeletal-muscle paralysis is indicated. Use pancuronium, 0.1 mg/kg IV (see p 472), or another nondepolarizing neuromuscular blocker. **Caution:** Be prepared to ventilate and endotracheally intubate the patient after muscle paralysis.

McGugan EA: Hyperpyrexia in the emergency department. *Emerg Med* (Fremantle) 2001;13(1):116–120. [PMID: 11476402] (Case report and review of causes of hyperpyrexia including heat stroke, NMS, malignant hypothermia, serotonin syndrome, and thyroid storm.)

Susman VL: Clinical management of neuroleptic malignant syndrome. *Psychiatr Q* 2001;72(4):325–336. [PMID: 11525080] (Review.)

OTHER COMPLICATIONS

I. Dystonia, dyskinesia, and rigidity

- A. Assessment.** Examples of drugs and toxins causing abnormal movements or rigidity are listed in Table I–15.
 1. **Dystonic reactions** are common with therapeutic or toxic doses of many antipsychotic agents and with some antiemetics. The mechanism triggering these reactions is thought to be related to central dopamine blockade. Dystonias usually consist of forced, involuntary, and often painful neck rotation (torticollis), tongue protrusion, jaw extension, or trismus. Other extrapyramidal or parkinsonian movement disorders (eg, pill rolling, bradykinesia, or masked facies) may also be seen with these agents.
 2. In contrast, **dyskinesias** are usually rapid, repetitive body movements that may involve small localized muscle groups (eg, tongue darting, focal my-

TABLE I-15. SELECTED DRUGS AND TOXINS CAUSING DYSTONIAS, DYSKINESIAS, AND RIGIDITY^a

Dystonia	Dyskinesias
Haloperidol and butyrophenones	Amphetamines
Metoclopramide	Anticholinergic agents
Phenothiazines (prochlorperazine)	Antihistamines
Rigidity	Caffeine
Black widow spider bite	Carbamazepine
Lithium	Carisoprodol
Malignant hyperthermia	Cocaine
Methaqualone	GHB (gamma hydroxybutyrate)
Monoamine oxidase inhibitors	Ketamine
Neuroleptic malignant syndrome	Levodopa
Phencyclidine (PCP)	Lithium
Strychnine	Phencyclidine (PCP)
Tetanus	Serotonin reuptake inhibitors (SSRIs)
	Tricyclic antidepressants

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:64.

oclonus) or may consist of generalized hyperkinetic activity. The cause is not dopamine blockade but, more commonly, increased dopamine effects or blockade of central cholinergic effects.

- 3. Rigidity** may also be seen with a number of toxins and may be caused by CNS effects or spinal cord stimulation. Neuroleptic malignant syndrome and serotonin syndrome (see p 22) are characterized by rigidity, hyperthermia, metabolic acidosis, and an altered mental status. Rigidity seen with malignant hyperthermia (see p 22) is caused by a defect at the muscle cell level and may not reverse with neuromuscular blockade.

B. Complications. Sustained muscular rigidity or hyperactivity may result in rhabdomyolysis (see p 27), hyperthermia (p 21), ventilatory failure (p 6), or metabolic acidosis (p 33).

C. Differential diagnosis. Rule out the following:

1. Catatonic rigidity caused by functional thought disorder.
2. Tetanus.
3. Cerebrovascular accident.
4. Postanoxic encephalopathy.
5. Idiopathic parkinsonism.

D. Treatment

1. Maintain the airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Check the rectal or tympanic temperature, and treat hyperthermia (see p 21) rapidly if the temperature is above 40°C (102.2°F).
3. **Dystonia.** Administer an anticholinergic agent such as diphenhydramine (Benadryl™; see p 436), 0.5–1 mg/kg IM or IV; or benztropine (Cogentin™; p 418), 1–4 mg IM in adults. Follow this treatment with oral therapy for 2–3 days.
4. **Dyskinesia.** Do not treat with anticholinergic agents. Instead, administer a sedative such as diazepam, 0.1–0.2 mg/kg IV (see p 415); lorazepam, 0.05–0.1 mg IV or IM; or midazolam, 0.05–0.1 mg/kg IV or 0.1–0.2 mg/kg IM (p 415).
5. **Rigidity.** Do not treat with anticholinergic agents. Instead, administer a sedative (see item 4, directly above) or provide specific pharmacologic therapy as follows:
 - a. Intravenous calcium (see p 424) or *Latrodectus* antivenom for a black widow spider bite (p 346).
 - b. Dantrolene (see p 431) for malignant hyperthermia (p 22).
 - c. Bromocriptine (see p 422) for neuroleptic malignant syndrome (p 22).

II. Rhabdomyolysis

- A. Assessment.** Muscle cell necrosis is a common complication of poisoning. Examples of drugs and toxins causing rhabdomyolysis are listed in Table I–16.
1. Causes of rhabdomyolysis include prolonged immobilization on a hard surface, excessive seizures or muscular hyperactivity, hyperthermia, or direct cytotoxic effects of the drug or toxin (eg, carbon monoxide, colchicine, *Amanita phalloides* mushrooms, and some snake venoms).
 2. The diagnosis is made by finding hematest-positive urine with few or no intact red blood cells or an elevated serum creatinine phosphokinase (CPK) level.
- B. Complications.** Myoglobin released by damaged muscle cells may precipitate in the kidneys, causing acute tubular necrosis and renal failure. This is more likely when the serum CPK level exceeds several thousand IU/L and if the patient is dehydrated. With severe rhabdomyolysis, hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia may also occur.
- C. Differential diagnosis.** Hemolysis with hemoglobinuria may also produce hematest-positive urine.
- D. Treatment**
1. Aggressively restore volume in dehydrated patients. Then establish a steady urine flow rate (3–5 mL/kg/h) with intravenous fluids. For massive rhabdomyolysis accompanied by oliguria, also consider a bolus of mannitol, 0.5 g/kg IV (see p 464).
 2. Alkalinize the urine by adding 100 mEq of sodium bicarbonate to each L of 5% dextrose. (Acidic urine promotes deposition of myoglobin in the tubules.)
 3. Provide intensive supportive care, including hemodialysis if needed, for acute renal failure. Kidney function is usually regained in 2–3 weeks.

III. Anaphylactic and anaphylactoid reactions

- A. Assessment.** Examples of drugs and toxins causing anaphylactic or anaphylactoid reactions are listed in Table I–17. These reactions are characterized by bronchospasm and increased vascular permeability that may lead to laryngeal edema, skin rash, and hypotension.
1. **Anaphylaxis** occurs when a patient with antigen-specific immunoglobulin E (IgE) bound to the surface of mast cells and basophils is exposed to the antigen, triggering the release of histamine and various other vasoactive compounds.
 2. **Anaphylactoid reactions** are also caused by release of active compounds from mast cells but do not involve prior sensitization or mediation through IgE.

TABLE I–16. SELECTED DRUGS AND TOXINS ASSOCIATED WITH RHABDOMYOLYSIS

Excessive muscular hyperactivity, rigidity, or seizures	Direct cellular toxicity
Amphetamines and derivatives	Amatoxin-containing mushrooms
Clozapine and olanzapine	Carbon monoxide
Cocaine	Colchicine
Lithium	Ethylene glycol
Monoamine oxidase inhibitors	Other or unknown mechanisms
Phencyclidine (PCP)	Barbiturates (prolonged immobility)
Seizures caused by a variety of agents	Chlorophenoxy herbicides
Strychnine	Ethanol
Tetanus	Gemfibrozil
Tricyclic antidepressants	Hemlock
	Hyperthermia caused by a variety of agents
	Sedative-hypnotic agents (prolonged immobility)
	“Statin” cholesterol drugs (eg, cerivastatin)
	Trauma

TABLE I-17. EXAMPLES OF DRUGS AND TOXINS CAUSING ANAPHYLACTIC OR ANAPHYLACTOID REACTIONS

Anaphylactic reactions (IgE-mediated)	Anaphylactoid reactions (not IgE-mediated)
Antisera (antivenins)	Acetylcysteine
Foods (nuts, fish, shellfish)	Blood products
Hymenoptera and other insect stings	Iodinated contrast media
Immunotherapy allergen extracts	Opiates
Penicillins and other antibiotics	Poisoning
Vaccines	Scombroid poisoning
	Tubocurarine
Other or unclassified	
Exercise	
Sulfites	
Tartrazine dye	

B. Complications. Severe anaphylactic or anaphylactoid reactions can result in laryngeal obstruction, respiratory arrest, hypotension, and death.

C. Differential diagnosis. Rule out the following:

1. Anxiety, with vasodepressor syncope or hyperventilation.
2. Pharmacologic effects of the drug or toxin (eg, procaine reaction with procaine penicillin).
3. Bronchospasm or laryngeal edema from irritant gas exposure.

D. Treatment

1. Maintain the airway and assist ventilation if necessary (see pp 1–7). Endotracheal intubation may be needed if laryngeal swelling is severe. Administer supplemental oxygen.
2. Treat hypotension with intravenous crystalloid fluids (eg, normal saline) and place the patient in a supine position.
3. Administer epinephrine (see p 442) as follows:
 - a. For mild to moderate reactions, administer 0.3–0.5 mg subcutaneously (SC) (children: 0.01 mg/kg, maximum 0.5 mg).
 - b. For severe reactions, administer 0.05–0.1 mg IV bolus every 5 minutes, or give an infusion starting at a rate of 1–4 mcg/min and titrating upward as needed.
4. Administer diphenhydramine (Benadryl; see p 436), 0.5–1 mg/kg IV over 1 minute. Follow with oral therapy for 2–3 days. Cimetidine (Tagamet™; p 428), 300 mg IV every 8 hours, is also helpful.
5. Administer a corticosteroid such as hydrocortisone, 200–300 mg IV; or methylprednisolone, 40–80 mg IV.

Holt SG, Moore KP: Pathogenesis and treatment of renal dysfunction in rhabdomyolysis. *Intensive Care Med* 2001;27(5):803–811. [PMID: 11430535] (Renal failure may be caused by renal vasoconstriction, tubular damage caused by oxidant injury, and possibly tubular obstruction.)

Rodnitzky RL: Drug-induced movement disorders. *Clin Neuropharmacol* 2002;25(3):142–152. [PMID: 12023568] (Review.)

DIAGNOSIS OF POISONING

Diagnosis and treatment of poisoning often must proceed rapidly without the results of extensive toxicologic screening. Fortunately, in most cases the correct diagnosis can be made by using carefully collected data from the history, a directed physical examination, and commonly available laboratory tests.

I. History. Although frequently unreliable or incomplete, the history of ingestion may be very useful if carefully obtained.

A. Ask the patient about all drugs taken, including nonprescription drugs, herbal medicines, and vitamins.

- B. Ask family members, friends, and paramedical personnel about any prescriptions or over-the-counter medications known to be used by the patient or others in the house.
- C. Obtain any available drugs or drug paraphernalia for later testing, but handle them very carefully to avoid poisoning by skin contact or an inadvertent needle stick with potential for hepatitis B or human immunodeficiency virus (HIV) transmission.
- D. Check with the pharmacy on the label of any medications found with the patient to determine whether other prescription drugs have been obtained there.

II. Physical examination

A. **General findings.** Perform a carefully directed examination emphasizing key physical findings that may uncover one of the common “autonomic syndromes.” Important variables in the autonomic physical examination include blood pressure, pulse rate, pupil size, sweating, and peristaltic activity. The autonomic syndromes are summarized in Table I–18.

- 1. **Alpha-adrenergic syndrome.** Hypertension with reflex bradycardia is characteristic of alpha-adrenergic syndrome. The pupils are usually dilated. (Examples: phenylpropanolamine, phenylephrine, and methoxamine.)
- 2. **Beta-adrenergic syndrome.** Beta-2–mediated vasodilation may cause hypotension. Tachycardia is common. (Examples: albuterol, metaproterenol, theophylline, and caffeine.)
- 3. **Mixed alpha- and beta-adrenergic syndrome.** Hypertension is accompanied by tachycardia. The pupils are dilated. The skin is sweaty, although mucous membranes are dry. (Examples: cocaine and amphetamines.)
- 4. **Sympatholytic syndrome.** Blood pressure and pulse rate are both decreased (peripheral alpha blockers may cause hypotension with reflex tachycardia). The pupils are small, often of pinpoint size. Peristalsis is often decreased. (Examples: centrally acting alpha-2 agonists [clonidine and methyldopa], opiates, and phenothiazines.)
- 5. **Nicotinic cholinergic syndrome.** Stimulation of nicotinic receptors at autonomic ganglia activates both parasympathetic and sympathetic systems, with unpredictable results. Excessive stimulation frequently causes depolarization blockage. Thus, initial tachycardia may be followed by bradycardia, and muscle fasciculations may be followed by paralysis. (Examples: nicotine; in addition, the depolarizing neuromuscular blocker succinylcholine, which acts on nicotinic receptors in skeletal muscle.)

TABLE I-18. AUTONOMIC SYNDROMES^{a,b}

	Blood Pressure	Pulse Rate	Pupil Size	Sweating	Peristalsis
Alpha-adrenergic	+	–	+	+	–
Beta-adrenergic	±	+	±	±	±
Mixed adrenergic	+	+	+	+	–
Sympatholytic	–	–	- -	–	–
Nicotinic	+	+	±	+	+
Muscarinic	–	- -	- -	+	+
Mixed cholinergic	±	±	- -	+	+
Anticholinergic	±	+	+	- -	- -

^aKey to symbols: + = increased; – = decreased; - - = markedly decreased; ± = mixed effect, no effect, or unpredictable.
^bAdapted, with permission, from Olson KR et al: *Med Toxicol* 1987;2:54.

6. **Muscarinic cholinergic syndrome.** Muscarinic receptors are located at effector organs of the parasympathetic system. Stimulation causes bradycardia, miosis, sweating, hyperperistalsis, bronchorrhea, wheezing, excessive salivation, and urinary incontinence. (Example: bethanechol.)
 7. **Mixed cholinergic syndrome.** Because both nicotinic and muscarinic receptors are stimulated, mixed effects may be seen. The pupils are usually miotic (of pinpoint size). The skin is sweaty, and peristaltic activity is increased. Fasciculations are a manifestation of nicotinic stimulation and may progress to muscle weakness or paralysis. (Examples: organophosphate and carbamate insecticides and physostigmine.)
 8. **Anticholinergic (antimuscarinic) syndrome.** Tachycardia with mild hypertension is common. The pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is common, and hyperthermia may occur. (Examples: atropine, scopolamine, benztropine, antihistamines, and antidepressants; all of these drugs are primarily antimuscarinic.)
- B. Eye findings**
1. **Pupil size** is affected by a number of drugs acting on the autonomic nervous system. Table I-19 lists common causes of miosis and mydriasis.
 2. Horizontal-gaze **nystagmus** is common with a variety of drugs and toxins, including barbiturates, ethanol, carbamazepine, phenytoin, and scorpion envenomation. Phencyclidine (PCP) may cause horizontal, vertical, and even rotatory nystagmus.
- C. Neuropathy.** A variety of drugs and poisons can cause sensory or motor neuropathy, usually after chronic repeated exposure (Table I-20). Some agents (eg, arsenic and thallium) can cause neuropathy after a single large exposure.
- D. Abdominal findings.** Peristaltic activity is commonly affected by drugs and toxins (see Table I-18 on autonomic syndromes).
1. Ileus may also be caused by **mechanical factors** such as injury to the gastrointestinal tract with perforation and peritonitis or mechanical obstruction by a swallowed foreign body.
 2. Abdominal distension and ileus may also be a manifestation of acute **bowel infarction**, a rare but catastrophic complication that results from prolonged hypotension or mesenteric artery vasospasm (caused, for ex-

TABLE I-19. SELECTED CAUSES OF PUPIL SIZE CHANGES^a

CONSTRICTED PUPILS (MIOSIS)	DILATED PUPILS (MYDRIASIS)
Sympatholytic agents	Sympathomimetic agents
Clonidine	Amphetamines and derivatives
Opiates	Cocaine
Phenothiazines	Dopamine
Tetrahydrozoline and oxymetazoline	LSD (lysergic acid diethylamide)
Valproic acid	Monoamine oxidase inhibitors
Cholinergic agents	Nicotine ^b
Carbamate insecticides	Anticholinergic agents
Nicotine ^b	Antihistamines
Organophosphates	Atropine and other anticholinergics
Physostigmine	Glutethimide
Pilocarpine	Tricyclic antidepressants
Others	
Heatstroke	
Pontine infarct	
Subarachnoid hemorrhage	

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:66.^bNicotine can cause pupils to be dilated (rare) or constricted (common).

TABLE I-20. SELECTED CAUSES OF NEUROPATHY

Cause	Comments
Acrylamide	Sensory and motor distal axonal neuropathy
Antineoplastic agents	Vincristine most strongly associated (see p 100)
Antiretroviral agents	Nucleoside reverse transcriptase inhibitors
Arsenic	Sensory predominant mixed axonal neuropathy (see p 115)
Buckthorn (<i>K. humboldtiana</i>)	Livestock and human demyelinating neuropathy
Carbon disulfide	Sensory and motor distal axonal neuropathy
Dimethylaminopropionitrile	Urogenital and distal sensory neuropathy
Disulfiram	Sensory and motor distal axonal neuropathy
Ethanol	Sensory and motor distal axonal neuropathy (see p 190)
<i>n</i> -Hexane	Sensory and motor distal axonal neuropathy
Isoniazid (INH)	Preventable with co-administration of pyridoxine (see p 233)
Lead	Motor predominant mixed axonal neuropathy (see p 238)
Mercury	Organic mercury compounds (see p 254)
Methyl <i>n</i> -butyl ketone	Acts like <i>n</i> -hexane, via 2,5-hexanedione metabolite
Nitrofurantoin	Sensory and motor distal axonal neuropathy
Nitrous oxide	Sensory axonal neuropathy with loss of proprioception (see p 282)
Organophosphate insecticides	Specific agents only (eg, triorthocresylphosphate)
Pyridoxine (Vitamin B ₆)	Sensory neuropathy with chronic excessive dosing
Selenium	Polyneuritis
Thallium	Sensory and motor distal axonal neuropathy (see p 352)
Tick paralysis	Ascending flaccid paralysis after bites by several tick species

ample, by ergot or amphetamines). Radiographs or CT scans may reveal air in the intestinal wall, biliary tree, or hepatic vein. The serum phosphorus and alkaline phosphatase levels are often elevated.

- 3. Vomiting, especially with hematemesis, may indicate the ingestion of a corrosive substance.

E. Skin findings

- 1. **Sweating** or absence of sweating may provide a clue to one of the autonomic syndromes (see Table I-18).
- 2. **Flushed red skin** may be caused by carbon monoxide poisoning, boric acid intoxication, chemical burns from corrosives or hydrocarbons, or anticholinergic agents. It may also result from vasodilation (eg, phenothiazines or disulfiram-ethanol interaction).
- 3. **Pale coloration** with diaphoresis is frequently caused by sympathomimetic agents. Severe localized pallor should suggest possible arterial vasospasm, such as that caused by ergot (see p 189) or some amphetamines (p 72).
- 4. **Cyanosis** may indicate hypoxia, sulfhemoglobinemia, or methemoglobinemia (see p 261).

F. **Odors.** A number of toxins may have characteristic odors (Table I-21). However, the odor may be subtle and may be obscured by the smell of emesis or by other ambient odors. In addition, the ability to smell an odor may vary; for example, only about 50% of the general population can smell the “bitter almond” odor of cyanide. Thus, the absence of an odor does not guarantee the absence of the toxin.

III. **Essential clinical laboratory tests.** Simple, readily available clinical laboratory tests may provide important clues to the diagnosis of poisoning and may guide the investigation toward specific toxicology testing.

A. **Routine tests.** The following tests are recommended for routine screening of the overdose patient:

- 1. Serum osmolality and osmolar gap.
- 2. Electrolytes for determination of sodium, potassium, and anion gap.
- 3. Serum glucose.

TABLE I-21. SOME COMMON ODORS CAUSED BY TOXINS AND DRUGS^a

Odor	Drug or Toxin
Acetone	Acetone, isopropyl alcohol
Acrid or pearlike	Chloral hydrate, paraldehyde
Bitter almonds	Cyanide
Carrots	Cicutoxin (water hemlock)
Garlic	Arsenic, organophosphates, selenium, thallium
Mothballs	Naphthalene, paradichlorobenzene
Pungent aromatic	Ethchlorvynol
Rotten eggs	Hydrogen sulfide, stibine, mercaptans, old sulfa drugs
Wintergreen	Methyl salicylate

^aAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:67.

- 4. Blood urea nitrogen (BUN) and creatinine for evaluation of renal function.
- 5. Hepatic transaminases and hepatic function tests.
- 6. Complete blood count or hemogram
- 7. Urinalysis to check for crystalluria, hemoglobinuria, or myoglobinuria.
- 8. Electrocardiogram (ECG).
- 9. Stat serum acetaminophen level and serum ethanol level.
- 10. Pregnancy test (females of childbearing age).

B. Serum osmolality and osmolar gap. Serum osmolality may be measured in the laboratory with the freezing-point-depression osmometer or the heat-of-vaporization osmometer. Under normal circumstances the measured serum osmolality is approximately 290 mOsm/L and can be calculated from the results of the sodium, glucose, and BUN tests. The difference between the calculated osmolality and the osmolality measured in the laboratory is the osmolar gap, more commonly referred to as the osmolar gap (Table I-22).

- 1. **Causes of an elevated osmolar gap** (Table I-22)
 - a. The osmolar gap may be increased in the presence of low-molecular-weight substances such as ethanol, other alcohols, and glycols, any of which can contribute to the measured but not the calculated osmolality. Table I-23 describes how to estimate alcohol and glycol levels based on the osmolar gap.
 - b. An osmolar gap accompanied by anion gap acidosis should immediately suggest poisoning by methanol or ethylene glycol. **Note:** A falsely normal osmolar gap despite the presence of alcohols may result from

TABLE I-22. CAUSES OF ELEVATED OSMOLAR GAP^a

Acetone	Mannitol
Dimethyl sulfoxide (DMSO)	Metaldehyde
Ethanol	Methanol
Ethyl ether	Osmotic contrast dyes
Ethylene glycol and other low-molecular-weight glycols	Propylene glycol
Isopropyl alcohol	Renal failure without dialysis
Magnesium	Severe alcoholic ketoacidosis, diabetic ketoacidosis, or lactic acidosis

^aOsmolar gap = measured – calculated osmolality. Normal = 0 ± 5 (many consider up to 10 as normal).

Calculated osmolality = $2[\text{Na}] = \frac{[\text{glucose}]}{18} + \frac{[\text{BUN}]}{2.8} = 290 \text{ mOsm/L}$

Na (serum sodium) in mEq/L; glucose and BUN (urea nitrogen) in mg/dL.

Note: The osmolality may be measured as falsely normal if a vaporization point osmometer is used instead of the freezing point device, because volatile alcohols will be boiled off.

TABLE I-23. ESTIMATION OF ALCOHOL AND GLYCOL LEVELS FROM THE OSMOLAR GAP^a

Alcohol or Glycol	Molecular Weight (mg/mmol)	Conversion Factor ^b
Acetone	58	5.8
Ethanol	46	4.6
Ethylene glycol	62	6.2
Isopropyl alcohol	60	6
Methanol	32	3.2
Propylene glycol	72	7.2

^aAdapted, with permission, from *Current Emergency Diagnosis & Treatment*, 3rd ed. Ho MT, Saunders CE (editors). New York: Appleton & Lange, 1990.

^bTo obtain estimated serum level (in mg/dL), multiply osmolar gap by conversion factor.

using a heat-of-vaporization method to measure osmolality, because the alcohols will boil off before the serum boiling point is reached.

2. Differential diagnosis

- Combined osmolar and anion gap elevation may also be seen with severe alcoholic ketoacidosis or diabetic ketoacidosis, due to accumulation of unmeasured anions (beta-hydroxybutyrate) and osmotically active substances (acetone, glycerol, and amino acids).
- Patients with chronic renal failure who are not undergoing hemodialysis may have an elevated osmolar gap owing to accumulation of low-molecular-weight solutes.
- False elevation of the osmolar gap may be caused by the use of an inappropriate sample tube (lavender top, ethylenediaminetetraacetic acid [EDTA]; gray top, fluoride-oxalate; blue top, citrate; see Table I-33, p 43).
- A falsely elevated gap may occur in patients with severe hyperlipidemia.

3. Treatment depends on the cause. If ethylene glycol (see p 194) or methanol (p 260) poisoning is suspected, based upon an elevated osmolar gap not accounted for by ethanol or other alcohols and on the presence of metabolic acidosis, then antidotal therapy (eg, ethanol [see p 444] or fomepizole [p 448]) and hemodialysis may be indicated.

C. Anion gap metabolic acidosis. The normal anion gap of 8–12 mEq/L accounts for unmeasured anions (eg, phosphate, sulfate, and anionic proteins) in the plasma. Metabolic acidosis is usually associated with an elevated anion gap.

1. Causes of elevated anion gap (Table I-24)

- An elevated anion gap acidosis is usually caused by an accumulation of lactic acid but may also be caused by other unmeasured acid anions such as formate (eg, methanol poisoning) or oxalate (eg, ethylene glycol poisoning).
- In any patient with an elevated anion gap, also check the osmolar gap; a combination of elevated anion and osmolar gaps suggests poisoning by methanol or ethylene glycol. **Note:** Combined osmolar and anion gap elevation may also be seen with severe alcoholic ketoacidosis and even diabetic ketoacidosis.
- A narrow anion gap may occur with an overdose by bromide or nitrate, both of which can increase the serum chloride level measured by some laboratory instruments. Also, high concentrations of lithium, calcium, and magnesium will narrow the anion gap due to lowering of the serum sodium concentration.

2. Differential diagnosis. Rule out the following:

- Common causes of lactic acidosis such as hypoxia or ischemia.

TABLE I-24. SELECTED DRUGS AND TOXINS CAUSING ELEVATED ANION GAP ACIDOSIS^{a,b}

Lactic acidosis	Other
Acetaminophen (levels >600 mg/L)	Alcoholic ketoacidosis
Antiretroviral drugs	Benzyl alcohol
Beta-adrenergic drugs	Diabetic ketoacidosis
Caffeine	Ethylene glycol
Carbon monoxide	Exogenous organic and mineral acids
Cyanide	Formaldehyde
Hydrogen sulfide	Ibuprofen (propionic acid)
Iron	Metaldehyde
Isoniazid (INH)	Methanol
Metformin and phenformin	Salicylates (salicylic acid)
Salicylates	Valproic acid
Seizures, shock, or hypoxia	
Sodium azide	
Theophylline	

^aAnion gap = $[Na] - [Cl] - [HCO_3^-] = 8 - 12$ mEq/L.

^bAdapted, in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:73.

- b. False depression of the serum bicarbonate and pCO_2 measurements, which can occur from incomplete filling of the red-topped Vacutainer™ blood collection tube.
- c. False depression of the pCO_2 and calculated bicarbonate measurements, which can result from excess heparin when obtaining arterial blood gases (0.25 mL heparin in 2 mL blood falsely lowers pCO_2 by about 8 mm and bicarbonate by about 5 mEq/L).

3. Treatment

- a. Treat the underlying cause of the acidosis.
 - (1) Treat seizures (see p 22) with anticonvulsants or neuromuscular paralysis.
 - (2) Treat hypoxia (see p 7) and hypotension (p 16) if they occur.
 - (3) Treat methanol (see p 260) or ethylene glycol (p 194) poisoning with fomepizole or ethanol and hemodialysis.
 - (4) Treat salicylate intoxication (see p 331) with alkaline diuresis and hemodialysis.
- b. Treatment of the acidemia itself is not generally necessary, unless the pH is less than 7–7.1. In fact, mild acidosis may be beneficial by promoting oxygen release to tissues. However, acidemia may be harmful in poisoning by salicylates or tricyclic antidepressants.
 - (1) In salicylate intoxication (see p 331), acidemia enhances salicylate entry into the brain and must be prevented. Alkalinization of the urine promotes salicylate elimination.
 - (2) In a tricyclic antidepressant overdose (see p 90), acidemia enhances cardiotoxicity. Maintain the serum pH at 7.45–7.5 with boluses of sodium bicarbonate.

D. Hyperglycemia and hypoglycemia. A variety of drugs and disease states can cause alterations in the serum glucose level (Table I-25). A patient's blood glucose level can be altered by nutritional state, endogenous insulin levels, and endocrine and liver functions and by the presence of various drugs or toxins.

- 1. **Hyperglycemia**, especially if severe (>500 mg/dL) or sustained, may result in dehydration and electrolyte imbalance caused by the osmotic effect of excess glucose in the urine; in addition, the shifting of water from the brain into plasma may result in hyperosmolar coma. More commonly, hyperglycemia in poisoning or drug overdose cases is mild and transient. Significant or sustained hyperglycemia should be treated if it is not resolving spontaneously or if the patient is symptomatic.

TABLE I-25. SELECTED CAUSES OF ALTERATIONS IN SERUM GLUCOSE

Hyperglycemia

Beta-2-adrenergic drugs
 Caffeine intoxication
 Corticosteroids
 Dextrose administration
 Diabetes mellitus
 Diazoxide
 Excessive circulating epinephrine
 Glucagon
 Theophylline intoxication
 Thiazide diuretics
 Vacor

Hypoglycemia

Akee fruit
 Endocrine disorders (hypopituitarism, Addison's disease, myxedema)
 Ethanol intoxication (especially pediatric)
 Fasting
 Hepatic failure
 Insulin
 Oral sulfonylurea hypoglycemic agents
 Pentamidine
 Propranolol intoxication
 Renal failure
 Salicylate intoxication
 Streptozocin
 Valproic acid intoxication

- a. If the patient has an altered mental status, maintain an open airway, assist ventilation if necessary, and administer supplemental oxygen (see pp 1–7).
 - b. Replace fluid deficits with intravenous normal saline (NS) or another isotonic crystalloid solution. Monitor serum potassium levels, which may fall sharply as blood glucose is corrected, and give supplemental potassium as needed.
 - c. Correct acid-base and electrolyte disturbances.
 - d. Administer regular insulin, 5–10 U IV initially, followed by infusion of 5–10 U/h, while monitoring the effects on serum glucose level (children: administer 0.1 U/kg initially and 0.1 U/kg/h).
- 2. Hypoglycemia**, if severe (serum glucose < 40 mg/dL) and sustained, can rapidly cause permanent brain injury. For this reason, whenever hypoglycemia is suspected as a cause of seizures, coma, or altered mental status, immediate empirical treatment with dextrose is indicated.
- a. If the patient has an altered mental status, maintain an open airway, assist ventilation if necessary, and administer supplemental oxygen (see pp 1–7).
 - b. If available, perform rapid bedside blood glucose testing (now possible in most emergency departments).
 - c. If the blood glucose is low (<70 mg/dL) or if bedside testing is not available, administer concentrated 50% dextrose, 50 mL IV (25 g). In children, give 25% dextrose, 2 mL/kg (see p 450).
 - d. In malnourished or alcoholic patients, also give thiamine, 100 mg IM or IV, to prevent acute Wernicke's syndrome.
 - e. For hypoglycemia caused by oral sulfonylurea drug overdose (see p 93), consider antidotal therapy with diazoxide (p 433) or octreotide (p 480).
- E. Hypernatremia and hyponatremia.** Sodium disorders occur infrequently in poisoned patients (see Table I–26). More commonly they are associated with underlying disease states. Antidiuretic hormone (ADH) is responsible for concentrating the urine and preventing excess water loss.
- 1. Hypernatremia** (serum sodium > 145 mEq/L) may be caused by excessive sodium intake, excessive free water loss, or impaired renal concentrating ability.
 - a. **Dehydration with normal kidney function.** Excessive sweating, hyperventilation, diarrhea, or osmotic diuresis (eg, hyperglycemia or mannitol administration) may cause disproportional water loss. The urine osmolality is usually greater than 400 mOsm/kg, and the ADH function is normal.

stimulate release of ADH. The urine sodium level is normally less than 10 mEq/L, unless the patient has been on diuretics.

- d. **Hyponatremia with normal volume** occurs in a variety of situations. Measurement of the serum and urine osmolalities may help determine the diagnosis.

- (1) **Syndrome of inappropriate ADH secretion (SIADH).** In patients with SIADH, ADH is secreted independently of volume or osmolality. Causes include malignancies, pulmonary disease, severe head injury, and some drugs (see Table I-26). The serum osmolality is low, but the urine osmolality is inappropriately increased (>300 mOsm/L). The serum blood urea nitrogen (BUN) is usually low (<10 mg/dL).
- (2) **Psychogenic polydipsia**, or compulsive water drinking (generally >10 L/d), causes reduced serum sodium because of the excessive free water intake and because the kidney excretes sodium to maintain euvolemia. The urine sodium level may be elevated, but urine osmolality is appropriately low because the kidney is attempting to excrete the excess water and ADH secretion is suppressed.
- (3) **Beer potomania** may result from chronic daily excessive beer drinking (>4 L/d). It usually occurs in patients with cirrhosis who already have elevated ADH levels.
- (4) Other causes of euvolemic hyponatremia include hypothyroidism, postoperative state, and idiosyncratic reactions to diuretics (generally thiazides).

4. **Treatment of hyponatremia.** Treatment depends on the cause, the patient's volume status, and most important, the patient's clinical condition.

Caution: Avoid overly rapid correction of the sodium, because brain damage (central pontine myelinolysis) may occur if the sodium is increased by more than 25 mEq/L in the first 24 hours. Obtain frequent measurements of serum and urine sodium levels and adjust the rate of infusion as needed to increase the serum sodium by no more than 1–1.5 mEq/h. Arrange consultation with a nephrologist as soon as possible. **For patients with profound hyponatremia** (serum sodium <110 mEq/L) accompanied by coma or seizures, administer hypertonic (3% sodium chloride) saline, 100–200 mL.

- a. **Hyponatremia with hypovolemia.** Replace lost volume with normal saline (0.9% sodium chloride, NS). If adrenal insufficiency is suspected, give hydrocortisone, 100 mg every 6–8 hours. Hypertonic saline (3% sodium chloride) is rarely indicated.

- b. **Hyponatremia with volume overload.** Restrict water (0.5–1 L/d) and treat the underlying condition (eg, congestive heart failure). If diuretics are given, do **not** allow excessive free water intake. Hypertonic saline is dangerous in these patients; if it is used, also administer furosemide, 0.5–1 mg/kg. Consider hemodialysis to reduce volume and restore the sodium level.

- c. **Hyponatremia with normal volume.** Asymptomatic patients may be treated conservatively with water restriction (0.5–1 L/d). Psychogenic compulsive water drinkers may have to be restrained or separated from all sources of water, including washbasins and toilets. Demeclocycline (a tetracycline antibiotic that can produce nephrogenic DI), 300–600 mg twice a day, can be used to treat mild chronic SIADH. (The onset of action may require a week.) For patients with coma or seizures, give hypertonic (3%) saline, 100–200 mL, along with furosemide, 0.5–1 mg/kg.

- F. **Hyperkalemia and hypokalemia.** A variety of drugs and toxins can cause serious alterations in the serum potassium level (Table I-27). Potassium levels are dependent on potassium intake and release (eg, from muscles), diuretic use, proper functioning of the ATPase pump, serum pH, and beta-adrenergic activity. Changes in serum potassium levels do not always reflect overall body

TABLE I-27. SELECTED DRUGS AND TOXINS AND OTHER CAUSES OF ALTERED SERUM POTASSIUM^a

Hyperkalemia	Hypokalemia
Acidosis	Alkalosis
Alpha-adrenergic agents	Barium
Angiotensin-converting enzyme (ACE) inhibitors	Beta-adrenergic drugs
Beta blockers	Caffeine
Digitalis glycosides	Diuretics (chronic)
Fluoride	Epinephrine
Lithium	Theophylline
Potassium	Toluene (chronic)
Renal failure	
Rhabdomyolysis	

^aAdapted in part, with permission, from Olson KR et al: *Med Toxicol* 1987;2:73.

gain or loss but may be caused by intracellular shifts (eg, acidosis drives potassium out of cells, but beta-adrenergic stimulation drives it into cells).

1. **Hyperkalemia** (serum potassium > 5 mEq/L) produces muscle weakness and interferes with normal cardiac conduction. Peaked T waves and prolonged PR intervals are the earliest signs of cardiotoxicity. Critical hyperkalemia produces widened QRS intervals, AV block, ventricular fibrillation, and cardiac arrest (see Figure I-5).

a. Hyperkalemia caused by **fluoride intoxication** (see p 200) is usually accompanied by hypocalcemia.

b. **Digitalis intoxication** associated with hyperkalemia is an indication for administration of digoxin-specific Fab antibodies (see p 434).

2. **Treatment of hyperkalemia.** A potassium level higher than 6 mEq/L is a medical emergency; a level greater than 7 mEq/L is critical.

a. Monitor the ECG. QRS prolongation indicates critical cardiac poisoning.

b. Administer calcium chloride, 10–20 mg/kg IV (see p 424), if there are signs of critical cardiac toxicity. **Caution:** Do **not** use calcium in patients with digitalis glycoside poisoning; intractable ventricular fibrillation may result.

c. Sodium bicarbonate, 1–2 mEq/kg IV (see p 419), rapidly drives potassium into cells and lowers the serum level.

d. Glucose plus insulin also promotes intracellular movement of potassium. Give 50% dextrose, 50 mL (25% dextrose, 2 mL/kg in children), plus regular insulin, 0.1 U/kg IV.

e. Inhaled beta-2 adrenergic agonists such as albuterol also enhance potassium entry into cells and can provide a rapid supplemental method of lowering serum potassium levels.

f. Kayexalate (sodium polystyrene sulfonate), 0.3–0.6 g/kg PO in 2 mL/kg 70% sorbitol, is effective but takes several hours.

g. Hemodialysis rapidly lowers serum potassium levels.

3. **Hypokalemia** (serum potassium < 3.5 mEq/L) may cause muscle weakness, hyporeflexia, and ileus. Rhabdomyolysis may occur. The ECG shows flattened T waves and prominent U waves. In severe hypokalemia, AV block, ventricular arrhythmias, and cardiac arrest may occur.

a. With **theophylline, caffeine, or beta-2 agonist** intoxication, an intracellular shift of potassium may produce a very low serum potassium level with normal total body stores. Patients usually do not have serious symptoms or ECG signs of hypokalemia, and aggressive potassium therapy is not required.

b. With **barium** poisoning (see p 127), profound hypokalemia may lead to respiratory muscle weakness and cardiac and respiratory arrest; therefore, intensive potassium therapy is necessary. Up to 420 mEq has been given in 24 hours.

- c. Hypokalemia resulting from **diuretic therapy** may contribute to ventricular arrhythmias, especially those associated with chronic digitalis glycoside poisoning.
- 4. **Treatment of hypokalemia.** Mild hypokalemia (potassium 3–3.5 mEq/L) is usually not associated with serious symptoms.
 - a. Administer potassium chloride orally or intravenously. See p 491 for recommended doses and the infusion rates.
 - b. Monitor serum potassium and the ECG for signs of hyperkalemia from excessive potassium therapy.
 - c. If hypokalemia is caused by diuretic therapy or gastrointestinal fluid losses, measure and replace other ions such as magnesium, sodium, and chloride.
- G. **Renal failure.** Examples of drugs and toxins causing renal failure are listed in Table I–28. Renal failure may be caused by a direct nephrotoxic action of the poison or acute massive tubular precipitation of myoglobin (rhabdomyolysis), hemoglobin (hemolysis), or calcium oxalate crystals (ethylene glycol); or it may be secondary to shock caused by blood or fluid loss or cardiovascular collapse.
- 1. **Assessment.** Renal failure is characterized by a progressive rise in the serum creatinine and blood urea nitrogen (BUN) levels, usually accompanied by oliguria or anuria.
 - a. The serum creatinine level usually rises about 1 mg/dL/d after total anuric renal failure.
 - b. A more abrupt rise should suggest rapid muscle breakdown (rhabdomyolysis), which increases the creatine load and also results in elevated creatine phosphokinase (CPK) levels that may interfere with determination of the serum creatinine level.
 - c. Oliguria may be seen before renal failure occurs, especially with hypovolemia, hypotension, or heart failure. In this case, the BUN level is usually elevated out of proportion to the serum creatinine level.
- 2. **Complications.** The earliest complication of acute renal failure is hyperkalemia (see p 38); this may be more pronounced if the cause of the renal failure is rhabdomyolysis or hemolysis, both of which release large amounts of intracellular potassium into the circulation. Later complications include metabolic acidosis, delirium, and coma.
- 3. **Treatment**
 - a. Prevent renal failure, if possible, by administering specific treatment (eg, acetylcysteine for acetaminophen overdose, British anti-Lewisite [BAL; dimercaprol] chelation for mercury poisoning, and intravenous fluids for rhabdomyolysis or shock).
 - b. Monitor the serum potassium level frequently and treat hyperkalemia (see p 38) if it occurs.

TABLE I–28. EXAMPLES OF DRUGS AND TOXINS AND OTHER CAUSES OF ACUTE RENAL FAILURE

Direct nephrotoxic effect	Hemolysis
Acetaminophen	Arsine
<i>Amanita phalloides</i> mushrooms	Naphthalene
<i>Amanita smithiana</i> mushrooms	Oxidizing agents (esp. with G6PD deficiency)
Analgesics (eg, ibuprofen, phenacetin)	Rhabdomyolysis (see also Table I–16)
Antibiotics (eg, aminoglycosides)	Amphetamines and cocaine
Bromates	Coma with prolonged immobility
Chlorates	Hyperthermia
Chlorinated hydrocarbons	Phencyclidine (PCP)
<i>Cortinarius</i> spp. mushrooms	Status epilepticus
Cyclosporin	Strychnine
Ethylene glycol (glycolate, oxalate)	
Heavy metals (eg, mercury)	

- c. Do **not** give supplemental potassium, and avoid cathartics or other medications containing magnesium, phosphate, or sodium.
- d. Perform hemodialysis as needed.
- H. **Hepatic failure.** A variety of drugs and toxins may cause hepatic injury (Table I-29). Mechanisms of toxicity include direct hepatocellular damage (eg, *Amanita phalloides* mushrooms [see p 273]), metabolic creation of a hepatotoxic intermediate (eg, acetaminophen [p 66] or carbon tetrachloride [p 154]), or hepatic vein thrombosis (eg, pyrrolizidine alkaloids; see Plants, p 309).
 - 1. **Assessment.** Laboratory and clinical evidence of hepatitis usually does not become apparent until at least 24–36 hours after exposure to the poison. Then transaminase levels rise sharply and may fall to normal over the next 3–5 days. If hepatic damage is severe, measurements of hepatic function (eg, bilirubin and prothrombin time) will continue to worsen after 2–3 days, even as transaminase levels are returning to normal. Metabolic acidosis and hypoglycemia usually indicate a poor prognosis.
 - 2. **Complications**
 - a. Abnormal hepatic function may result in excessive bleeding owing to insufficient production of vitamin K–dependent coagulation factors.
 - b. Hepatic encephalopathy may lead to coma and death, usually within 5–7 days, of massive hepatic failure.
 - 3. **Treatment**
 - a. Prevent hepatic injury if possible by administering specific treatment (eg, acetylcysteine for acetaminophen overdose).
 - b. Obtain baseline and daily transaminase, bilirubin, and glucose levels and prothrombin time.
 - c. Provide intensive supportive care for hepatic failure and encephalopathy (eg, glucose for hypoglycemia, fresh frozen plasma for coagulopathy, or lactulose for encephalopathy).
 - d. Liver transplantation may be the only effective treatment once massive hepatic necrosis has resulted in severe encephalopathy.
- IV. **Toxicology screening.*** To maximize the utility of the toxicology laboratory, it is necessary to understand what the laboratory can and cannot do and how knowledge of the results will affect the patient. Comprehensive blood and urine screening is of little practical value in the initial care of the poisoned patient. On the other hand, specific toxicologic analyses and quantitative levels of certain drugs may be extremely helpful. Before ordering any tests, always ask these two questions: (i) How will the result of the test alter the approach to treatment, and (ii) can the result of the test be returned in time to affect therapy positively?
 - A. **Limitations of toxicology screens.** Owing to long turnaround time, lack of availability, reliability factors, and the low risk of serious morbidity with supportive clinical management, toxicology screening is estimated to affect management in less than 15% of all cases of poisoning or drug overdose.

*By John D. Osterloh, MD.

TABLE I-29. EXAMPLES OF DRUGS AND TOXINS CAUSING HEPATIC DAMAGE

Acetaminophen	2-Nitropropane
<i>Amanita phalloides</i> and similar mushrooms	Nitrosamine
Arsenic	Pennyroyal oil
Carbon tetrachloride and other chlorinated hydrocarbons	Phenol
Copper	Phosphorus
Dimethylformamide	Polychlorinated biphenyls (PCBs)
Ethanol	Pyrrolizidine alkaloids (see Plants, p 309)
<i>Gyrometra</i> mushrooms	Thallium
Halothane	Troglitazone
Iron	Valproic acid

- 1. Comprehensive toxicology screens or panels may look specifically for only 40–100 drugs out of more than 10,000 possible drugs or toxins (or 6 million chemicals). However, these 40–50 drugs (Tables I–30 and I–31) account for more than 80% of overdoses.
- 2. To detect many different drugs, comprehensive screens usually include multiple methods with broad specificity, and sensitivity may be poor for some drugs (resulting in analytic false-negative results). On the other hand, some drugs present in therapeutic amounts may be detected on the screen even though they are causing no clinical symptoms (clinical false-positives).
- 3. Because many agents are neither sought nor detected during a toxicology screening (Table I–32), a negative result does not always rule out poisoning; the negative predictive value of the screen is only about 70%. In contrast, a positive result has a predictive value of about 90%.
- 4. The specificity of toxicologic tests is dependent on the method and the laboratory. The presence of other drugs, drug metabolites, disease states, or incorrect sampling may cause erroneous results (Table I–33).
- 5. **Adulteration** of urine may be attempted by persons undergoing enforced drug testing in order to evade drug detection. Methods used include dilu-

TABLE I-30. DRUGS COMMONLY INCLUDED IN A COMPREHENSIVE URINE SCREEN^a

Alcohols	Thioridazine
Acetone	Promethazine
Ethanol	Thioridazine
Isopropyl alcohol	Trifluoperazine
Methanol	Sedative-hypnotic drugs
Analgesics	Barbiturates ^c
Acetaminophen	Benzodiazepines ^c
Salicylates	Carisoprodol
Anticonvulsants	Chloral hydrate
Carbamazepine	Ethchlorvynol
Phenobarbital	Glutethimide
Phenytoin	Meprobamate
Primidone	Methaqualone
Antihistamines	Stimulants
Benztrapine	Amphetamines ^c
Chlorpheniramine	Caffeine
Diphenhydramine	Cocaine and benzoylecgonine
Pyrilamine	Phencyclidine (PCP)
Trihexylphenidyl	Strychnine
Opiates	Tricyclic antidepressants
Codeine	Amitriptyline
Dextromethorphan	Desipramine
Hydrocodone	Doxepin
Meperidine	Imipramine
Methadone	Nortriptyline
Morphine	Protriptyline
Oxycodone ^b	Cardiac drugs
Pentazocine	Diltiazem
Propoxyphene	Lidocaine
Phenothiazines	Procainamide
Chlorpromazine	Propranolol
Prochlorperazine	Quinidine and quinine
Promethazine	Verapamil

^aNewer drugs in any category may not be included in screening.

^bDepends on the order of testing.

^cNot all drugs in this class are detected.

TABLE I-31. DRUGS COMMONLY INCLUDED IN A HOSPITAL “DRUGS OF ABUSE” PANEL^a

Drug	Detection Time Window for Recreational Doses	Comments
Amphetamines	2 days	Often misses MDA or MDMA; many false positives (see Table I-33)
Barbiturates	Less than 2 days for most drugs, up to 1 week for phenobarbital	
Benzodiazepines	2–7 days (varies with specific drug and duration of use)	May not detect triazolam, lorazepam, alprazolam
Cocaine	2 days	Detects metabolite benzoylecgonine
Ethanol	Less than 1 day	
Marihuana (THC)	2–5 days after single use (longer for chronic use)	
Opiates	2–3 days	Synthetic opioids (meperidine, methadone, propoxyphene, oxycodone) are not detected; separate testing for methadone is sometimes offered. (see also Table 1–33)
Phencyclidine (PCP)	Up to 7 days	False positives (see Table I-33)

^aLabs often perform only some of these tests, depending on what their emergency department requests and local patterns of drug use in the community. Also, positive results are usually not confirmed with a second, more specific test; thus, false positives may be reported.

tion (ingested or added water); addition of acids, baking soda, bleach, metal salts, nitrite salts, glutaraldehyde, or pyridinium chlorochromate. The intent is to inactivate, either chemically or biologically, the initial screening immunoassay to produce a negative test. Adulteration is variably successful depending on the agent used and the type of immunoassay. Laboratories that routinely perform urine testing for drug surveillance programs often have methods to test for some of the adulterants as well assay indicators that suggest possible adulterations.

B. Uses for toxicology screens

- 1. **Comprehensive screening** of urine and blood should be carried out whenever the diagnosis of brain death is being considered, to rule out the

TABLE I-32. DRUGS AND TOXINS **NOT** COMMONLY INCLUDED IN EMERGENCY TOXICOLOGIC SCREENING PANELS^a

Anesthetic gases	Ethylene glycol
Antiarrhythmic agents	Fentanyl and other opiate derivatives
Antibiotics	Fluoride
Antidepressants (newer)	Formate (formic acid, from methanol poisoning)
Antihypertensives	Hypoglycemic agents
Antipsychotic agents (newer)	Isoniazid (INH)
Benzodiazepines (newer)	Lithium
Beta blockers other than propranolol	LSD (lysergic acid diethylamide)
Borate	MAO inhibitors
Bromide	Noxious gases
Calcium antagonists (newer)	Plant, fungal, and microbiologic toxins
Colchicine	Pressors (eg, dopamine)
Cyanide	Solvents and hydrocarbons
Digitalis glycosides	Theophylline
Diuretics	Valproic acid
Ergot alkaloids	Vasodilators

^aMany of these are available as separate specific tests.

TABLE I-33. INTERFERENCES IN TOXICOLOGIC BLOOD OR URINE TESTS

Drug or Toxin	Method ^a	Causes of Falsely Increased Level
Acetaminophen	SC ^b	Salicylate, salicylamide, methyl salicylate (each will increase acetaminophen level by 10% of their level in mg/L); bilirubin; phenols; renal failure (each 1 mg/dL increase in creatinine can increase acetaminophen by 30 mg/L).
	GC, IA	Phenacetin.
	HPLC ^b	Cephalosporins; sulfonamides.
Amitriptyline	HPLC, GC	Cyclobenzaprine.
Amphetamines (urine)	GC ^c	Other volatile stimulant amines (misidentified). GC mass spectrometry poorly distinguishes <i>d</i> -methamphetamine from <i>l</i> -methamphetamine (found in Vicks™ inhaler).
	IA ^c , TLC ^c	Many false positives: cross-reacting stimulant drugs (ephedrine, fenfluramine, MDA, MDMA, phentermine, phenmetrazine, pseudoephedrine, and other amphetamine analogs); cross-reacting nonstimulant drugs (bupropion, chlorpromazine, labetalol, ranitidine, sertraline, trazodone, trimethobenzamide); drugs metabolized to amphetamines (benzphetamine, clobenzorex, famprofazone, fenproporex, selegiline).
Benzodiazepines	IA	Oxaprozin and many other NSAIDs may falsely lower the result.
Chloride	SC, EC	Bromide (variable interference).
Creatinine	SC ^b	Ketoacidosis (may increase Cr up to 2–3 mg/dL in nonrate methods); cephalosporins; creatine (eg, with rhabdomyolysis).
	EZ	Creatine, lidocaine metabolite, 5-fluorouracil, nitromethane “fuel.”
Cyanide	SC	Thiosulfate.
Digoxin	IA	Endogenous digoxinlike natriuretic substances in newborns and in patients with hypervolemic states (cirrhosis, heart failure, uremia, pregnancy) and renal failure (up to 0.5 ng/mL); plant or animal glycosides (bufotoxins; Chan Su; oleander); after digoxin antibody (Fab) administration (with tests that measure total serum digoxin); presence of heterophile or human antimouse antibodies (up to 45.6 ng/mL reported in one case).
	MEIA	Falsely lowered serum digoxin concentrations during therapy with spironolactone, canrenone.
Ethanol	SC ^b	Other alcohols, ketones (by oxidation methods).
	EZ	Isopropyl alcohol; patient with elevated lactate and LDH
Ethylene glycol	EZ	Other glycols; elevated triglycerides.
	GC	Propylene glycol (may also decrease the ethylene glycol level).
Glucose	EC, EZ	Acetaminophen (increases); ascorbate decreases urine glucose level (Medisense™ device).
	Any method	Glucose level may fall by up to 30 mg/dL/h when transport to lab is delayed (does not occur if specimen is collected in gray-top tube).
Iron	SC	Deferoxamine causes 15% lowering of total iron-binding capacity (TIBC); lavender-top Vacutainer tube contains EDTA, which lowers total iron.

(continued)

TABLE I-33. INTERFERENCES IN TOXICOLOGIC BLOOD OR URINE TESTS (CONTINUED)

Drug or Toxin	Method ^a	Causes of Falsely Increased Level
Isopropanol	GC	Skin disinfectant containing isopropyl alcohol used before venipuncture (highly variable, usually trivial, but up to 40 mg/dL).
Ketones	SC	Acetylcysteine; valproic acid; captopril; levodopa.
Lithium	FE, SC	Green-top Vacutainer specimen tube (may contain lithium heparin) can cause marked elevation (up to 6–8 mEq/L).
	SC	Procainamide, quinidine can produce 5–15% elevation.
Methadone (urine)	IA	Diphenhydramine, verapamil, disopyramide.
Methemoglobin	SC	Sulfhemoglobin (cross-positive ~10% by co-oximeter); methylene blue (2 mg/kg dose gives transient false-positive 15% methemoglobin level); hyperlipidemia (triglyceride level of 6000 mg/dL may give false methemoglobin of 28.6%).
		Falsely decreased level with in vitro spontaneous reduction to hemoglobin in Vacutainer tube (~10%/h). Analyze within 1 hour.
Morphine/codeine (urine)	TLC ^c	Hydromorphone; hydrocodone; oxycodone (misidentification).
	IA ^c	Cross-reactant opioids: hydrocodone; hydromorphone; monoacetylmorphine; morphine from poppy-seed ingestion (oxycodone usually not detected by IA except in overdose amounts); also rifampin and ofloxacin and other quinolones in different IAs.
Osmolality	Osm	Lavender-top (EDTA) Vacutainer specimen tube (15 mOsm/L); gray-top (fluoride-oxalate) tube (150 mOsm/L); blue-top (citrate) tube (10 mOsm/L); green-top (lithium heparin) tube (theoretically, up to 6–8 mOsm/L).
		Falsely normal if vapor pressure method used (alcohols are volatilized).
Phencyclidine (urine)	IA ^c	Diphenhydramine; methadone; dextromethorphan; chlorpromazine.
Salicylate	SC	Phenothiazines (urine); diflunisal; ketosis ^c ; salicylamide; accumulated salicylate metabolites in patients with renal failure (~10% increase).
	EZ	Acetaminophen (slight salicylate elevation).
	IA, SC	Diflunisal.
	SC	Decreased or altered salicylate level: bilirubin; phenylketones.
Theophylline	HPLC ^b	Acetazolamide; cephalosporins; endogenous xanthines and accumulated theophylline metabolites in renal failure (minor effect).
	IA	Caffeine overdose; accumulated theophylline metabolites in renal failure.
Tricyclic antidepressants	IA	Carbamazepine, quetiapine.

^aGC = gas chromatography (interferences primarily with older methods); HPLC = high-pressure liquid chromatography; IA = immunoassay; SC = spectrochemical; TLC = thin-layer chromatography; EC = electrochemical; EZ = enzymatic; FE = flame emission; MEIA = microparticle enzymatic immunoassay.

^bUncommon methodology.

^cMore common with urine test. Confirmation by a second test is required. *Note:* urine testing is sometimes affected by intentional adulteration to avoid drug detection (see text).

presence of common depressant drugs that might result in temporary loss of brain activity and mimic brain death. Toxicology screens may be used to confirm clinical impressions during hospitalization and can be inserted in the permanent medicolegal record. This may be important if homicide, assault, or child abuse is suspected.

- 2. **Selective screens** (eg, for “drugs of abuse”) with rapid turnaround times are often used to confirm clinical impressions and may aid in disposition of the patient. Positive results should be subjected to confirmatory testing with a second method.

C. Approach to toxicology testing

- 1. Communicate clinical suspicions to the laboratory.
- 2. Obtain blood and urine specimens on admission in unusual cases and have the laboratory store them temporarily. If the patient rapidly recovers, they can be discarded.
- 3. Urine is usually the best sample for broad qualitative screening. Blood samples should be saved for possible quantitative testing, but blood is not a good specimen for screening for many common drugs, including psychotropic agents, opiates, and stimulants.
- 4. Decide if a specific quantitative blood level may assist in management decisions (eg, use of an antidote or dialysis; Table I–34). Quantitative levels are helpful only if there is a predictable correlation between the serum level and toxic effects.
- 5. A regional poison control center (see Table I–42) or toxicology consultant may provide assistance in considering certain drug etiologies and in selecting specific tests.

V. **Abdominal x-rays.** Abdominal x-rays may reveal radiopaque tablets, drug-filled condoms, or other toxic material.

- A. The radiograph is useful only if positive; recent studies suggest that few types of tablets are predictably visible (Table I–35).
- B. Do **not** attempt to determine the radiopacity of a tablet by placing it directly on the x-ray plate. This often produces a false-positive result because of an air contrast effect.

TABLE I–34. SPECIFIC QUANTITATIVE LEVELS AND POTENTIAL INTERVENTIONS^a

Drug or Toxin	Potential Intervention
Acetaminophen	Acetylcysteine
Carbamazepine	Repeat-dose charcoal, hemoperfusion
Carboxyhemoglobin	100% oxygen
Digoxin	Digoxin-specific antibodies
Ethanol	Low level indicates search for other toxins
Ethylene glycol	Ethanol or fomepizole therapy, hemodialysis
Iron	Deferoxamine chelation
Lithium	Hemodialysis
Methanol	Ethanol or fomepizole therapy, hemodialysis
Methemoglobin	Methylene blue
Salicylate	Alkalinization, hemodialysis
Theophylline	Repeat-dose charcoal, hemoperfusion
Valproic acid	Hemodialysis, repeat-dose charcoal

^aFor specific guidance see individual chapters in Section II.

TABLE I-35. RADIOPAQUE DRUGS AND POISONS^a**Usually visible**

Bismuth subsalicylate (Pepto-Bismol)
 Calcium carbonate (Tums)
 Iron tablets
 Lead and lead-containing paint
 Metallic foreign bodies
 Potassium tablets

Sometimes/weakly visible

Acetazolamide
 Arsenic
 Brompheniramine and dexbrompheniramine
 Busulfan
 Chloral hydrate
 Enteric-coated or sustained-release preparations (highly variable)
 Meclizine
 Perphenazine with amitriptyline
 Phosphorus
 Prochlorperazine
 Sodium chloride
 Thiamine
 Tranlycypromine
 Trifluoperazine
 Trimiprazine
 Zinc sulfate

[PMID: 11719745] (Prospective evaluation of intoxicated patients suggests that the serum ethanol concentration [in mg/dL] is approximately 3.7 times the osmolar gap.)

DECONTAMINATION

I. Surface decontamination

A. Skin. Corrosive agents rapidly injure the skin and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action. Table II–20 (p 158) lists several corrosive chemical agents that can have systemic toxicity, and many of them are readily absorbed through the skin.

1. Be careful not to expose yourself or other care providers to potentially contaminating substances. Wear protective gear (gloves, gown, and goggles) and wash exposed areas promptly. Contact a regional poison center for information about the hazards of the chemicals involved; in the majority of cases, health-care providers are not at significant personal risk for secondary contamination, and simple measures such as emergency department gowns and plain latex gloves are sufficient protection. For radiation and other hazardous materials incidents, see also Section IV (p 510).
2. Remove contaminated clothing and flush exposed areas with copious quantities of tepid (lukewarm) water or saline. Wash carefully behind ears, under nails, and in skin folds. Use soap and shampoo for oily substances.
3. There is rarely a need for chemical neutralization of a substance spilled on the skin. In fact, the heat generated by chemical neutralization can potentially create worse injury. Some of the few exceptions to this rule are listed in Table I–36.

TABLE I-36. SOME TOPICAL AGENTS FOR CHEMICAL EXPOSURES TO THE SKIN^a

Chemical Corrosive Agent	Topical Treatment
Hydrofluoric acid	Calcium soaks
Oxalic acid	Calcium soaks
Phenol	Mineral oil or other oil; isopropyl alcohol
Phosphorus (white)	Copper sulfate 1% (colors embedded granules blue, facilitates removal)

^aReference: Edelman PA: Chemical and electrical burns. In: *Management of the Burned Patient*, Achauer BM (editor). New York: Appleton & Lange, 1987, pp. 183–202.

B. Eyes. The cornea is especially sensitive to corrosive agents and hydrocarbon solvents that may rapidly damage the corneal surface and lead to permanent scarring.

1. Act quickly to prevent serious damage. Flush exposed eyes with copious quantities of tepid tap water or saline. If available, instill local anesthetic drops in the eye first to facilitate irrigation. Remove the victim's contact lenses if they are being worn.
2. Place the victim in a supine position under a tap or use intravenous tubing to direct a stream of water across the nasal bridge into the medial aspect of the eye (Figure I-8). Use at least 1 L to irrigate each eye.
3. If the offending substance is an acid or a base, check the pH of the victim's tears after irrigation and continue irrigation if the pH remains abnormal.
4. Do not instill any neutralizing solution; there is no evidence that such treatment works, and it may further damage the eye.
5. After irrigation is complete, check the conjunctival and corneal surfaces carefully for evidence of full-thickness injury. Perform a fluorescein examination of the eye by using fluorescein dye and a Wood's lamp to reveal corneal injury.
6. Patients with serious conjunctival or corneal injury should be referred to an ophthalmologist immediately.

C. Inhalation. Agents that injure the pulmonary system may be acutely irritating gases or fumes and may have good or poor warning properties (see p 213).

1. Be careful not to expose yourself or other care providers to toxic gases or fumes without adequate respiratory protection (see p 515).
2. Remove the victim from exposure and give supplemental humidified oxygen, if available. Assist ventilation if necessary (see pp 1–7).
3. Observe closely for evidence of upper respiratory tract edema, which is heralded by a hoarse voice and stridor and may progress rapidly to complete airway obstruction. Endotracheally intubate patients who show evidence of progressive airway compromise.
4. Also observe for late-onset noncardiogenic pulmonary edema resulting from slower-acting toxins, which may take several hours to appear. Early signs and symptoms include dyspnea, hypoxemia, and tachypnea (see p 213).

II. Gastrointestinal decontamination. There remains some controversy about the roles of emesis, gastric lavage, activated charcoal, and cathartics to decontaminate the gastrointestinal tract. There is little support in the medical literature for gut-emptying procedures, and studies have shown that after a delay of 60 minutes or more, very little of the ingested dose is removed by emesis or gastric lavage. Moreover, recent studies suggest that, in the typical overdosed patient, simple oral administration of activated charcoal without prior gut emptying is probably just as effective as the traditional sequence of gut emptying followed by charcoal.

On the other hand, there are some circumstances where aggressive gut decontamination may potentially be life saving, even after more than 1–2 hours. Examples include ingestion of highly toxic drugs (eg, calcium channel blockers,

FIGURE I-8. Irrigation of the eyes after chemical injury, showing technique for irrigating both upper and lower eyelids.

colchicine), ingestion of drugs not adsorbed to charcoal (eg, iron, lithium), ingestion of massive amounts of a drug (eg, 150–200 aspirin tablets), or ingestion of sustained-release or enteric-coated products.

A. Emesis. Syrup of ipecac-induced emesis is no longer the treatment of choice for any ingestions. It might be employed in rare situations when medical care is expected to be delayed more than 60 minutes *and if the ipecac can be given within a few minutes of the ingestion*. Ipecac is no longer used in most emergency departments because of the ready availability of activated charcoal. After syrup of ipecac administration, vomiting usually occurs within 20–30 minutes. If the ingestion occurred more than 30–60 minutes before ipecac administration, emesis is not very effective. Moreover, persistent vomiting after ipecac use is likely to delay the administration of activated charcoal (see item C, below).

1. Indications

- a. Early prehospital management of selected (see Contraindications below) potentially serious oral poisonings, particularly in the home immediately after ingestion, when other measures (eg, activated charcoal) are not available and transport time to a medical facility may be prolonged (eg, more than 1 hour).
- b. Possibly useful to remove ingested agents not adsorbed by activated charcoal (eg, iron, lithium, potassium). However, most of these cases are preferably managed with whole-bowel irrigation (see below).

2. Contraindications

- a. Obtunded, comatose, or convulsing patient.
- b. Ingestion of a substance likely to cause onset of CNS depression seizures within a short clinical time frame (eg, opioids, sedative-hypnotic agents, tricyclic antidepressants, camphor, cocaine, isoniazid, or strychnine).
- c. Ingestion of a corrosive agent (eg, acids, alkali, or strong oxidizing agents).
- d. Ingestion of a simple aliphatic hydrocarbon (see p 219). These are likely to cause pneumonitis if aspirated, but usually do not cause systemic poisoning once they enter the stomach. For those hydrocarbons that do carry a potential for systemic toxicity, activated charcoal with or without gastric lavage is preferable.

3. Adverse effects

- a. Persistent vomiting may delay administration of activated charcoal or oral antidotes (eg, acetylcysteine).
- b. Protracted forceful vomiting may result in hemorrhagic gastritis or a Mallory-Weiss tear.
- c. Vomiting may promote passage of toxic material into the small intestine, enhancing absorption.
- d. Drowsiness occurs in about 20% and diarrhea in 25% of children.
- e. Repeated daily use (eg, by bulimic patients) may result in cardiac arrhythmias and cardiomyopathy owing to accumulation of cardiotoxic alkaloids.

4. Technique. Use only syrup of ipecac, not the fluid extract (which contains much higher concentrations of emetic and cardiotoxic alkaloids).

- a. Administer 30 mL of syrup of ipecac orally (15 mL for children under age 5 years; 10 mL for children under age 1 year; not recommended for children under age 6 months). After 10–15 minutes, give 2–3 glasses of water (there is no consensus on the quantity of water or the timing of administration).
- b. If emesis has not occurred after 20 minutes, a second dose of ipecac may be given. Repeat the fluid administration. Have the patient sit up or move around, because this sometimes stimulates vomiting.
- c. If the second dose of ipecac does not induce vomiting, use an alternative method of gut decontamination (eg, activated charcoal). It is not necessary to empty the stomach just to remove the ipecac.
- d. A soapy water solution may be used as an alternate emetic. Use only standard dishwashing liquid or lotion soap, two tablespoons in a glass of water. Do **not** use powdered laundry or dishwasher detergent or liquid dishwashing concentrate; these products are corrosive. There is no other acceptable alternative to syrup of ipecac. Manual digital stimulation, copper sulfate, salt water, mustard water, apomorphine, and other emetics are unsafe and should not be used.

B. Gastric lavage. Gastric lavage is a more invasive procedure than ipecac-induced emesis, but it is still occasionally used in hospital emergency departments. Although there is little evidence to support its use, gastric lavage is probably slightly more effective than ipecac, especially for recently ingested liquid substances. However, it does not reliably remove undissolved pills or pill fragments (especially sustained-release or enteric-coated products). In addition, the procedure may delay administration of activated charcoal and may hasten the movement of drugs and poisons into the small intestine, especially if the patient is supine or in the right decubitus position. Gastric lavage is not necessary for small to moderate ingestions of most substances if activated charcoal can be given promptly.**1. Indications**

- a. To remove ingested liquid and solid drugs and poisons when the patient has taken a massive overdose or a particularly toxic substance. Lavage

is more likely to be effective if initiated within 30–60 minutes of the ingestion, although it may still be useful several hours after ingestion of agents that slow gastric emptying (eg, salicylates or anticholinergic drugs).

- b. To administer activated charcoal and whole-bowel irrigation to patients unwilling or unable to swallow them.
- c. To dilute and remove corrosive liquids from the stomach and to empty the stomach in preparation for endoscopy.

2. Contraindications

- a. Obtunded, comatose, or convulsing patients. Because it may disturb the normal physiology of the esophagus and airway protective mechanisms, gastric lavage must be used with caution in obtunded patients whose airway reflexes are dulled. In such cases, endotracheal intubation with a cuffed endotracheal tube should be performed first to protect the airway.
- b. Ingestion of sustained-release or enteric-coated tablets. (Due to the size of most tablets lavage is unlikely to return intact tablets, even through a 40F orogastric hose.) In such cases, whole-bowel irrigation (see p 52) is preferable.
- c. Use of gastric lavage after ingestion of a corrosive substance is controversial; some gastroenterologists recommend that lavage be performed as soon as possible after liquid caustic ingestion to remove corrosive material from the stomach and to prepare for endoscopy.

3. Adverse effects

- a. Perforation of the esophagus or stomach.
- b. Nosebleed from nasal trauma during passage of the tube.
- c. Inadvertent tracheal intubation.
- d. Vomiting resulting in pulmonary aspiration of gastric contents in an obtunded patient without airway protection.

4. Technique (Figure 1–9)

- a. If the patient is deeply obtunded, protect the airway by intubating the trachea with a cuffed endotracheal tube.
- b. Place the patient in the left lateral decubitus position. This helps prevent ingested material from being pushed into the duodenum during lavage.
- c. Insert a large gastric tube through the mouth or nose and into the stomach (36–40F [catheter size] in adults; a smaller tube will suffice for liquid poisons or if simple administration of charcoal is all that is intended). Check tube position with air insufflation while listening with a stethoscope positioned on the patient's stomach.
- d. Withdraw as much of the stomach contents as possible. If the ingested poison is a toxic chemical that may contaminate hospital personnel (eg, cyanide, organophosphate insecticide, etc), take steps to immediately isolate it (eg, use a self-contained wall suction unit).
- e. Administer activated charcoal, 60–100 g (1 g/kg; see item C, below), down the tube before starting lavage to begin adsorption of material that may enter the intestine during the lavage procedure.
- f. Instill tepid (lukewarm) water or saline, 200- to 300-mL aliquots, and remove by gravity or active suction. Use repeated aliquots for a total of 2 L or until the return is free of pills or toxic material. **Caution:** Use of excessive volumes of lavage fluid or plain tap water can result in hypothermia or electrolyte imbalance in infants and small children.

C. Activated charcoal. Activated charcoal is a highly adsorbent powdered material made from a distillation of wood pulp. Owing to its very large surface area, it is highly effective in adsorbing most toxins. Only a few toxins are poorly adsorbed to charcoal (Table 1–37). Numerous studies suggest that activated charcoal given alone without prior gastric emptying is as effective as or even more effective than emesis and lavage procedures (see items A and B, above).

1. Indications

- a. Used after virtually any toxic ingestion to limit drug absorption from the gastrointestinal tract.

FIGURE I-9. Gastric lavage.

- b. Charcoal is usually given even if the offending substance is not known to be well adsorbed to charcoal, in case other substances have been co-ingested.
- c. Repeated oral doses of activated charcoal may enhance elimination of some drugs from the bloodstream (see p 57).
2. **Contraindications.** Ileus without distension is not a contraindication for a single dose of charcoal, but further doses should be withheld.
3. **Adverse effects**
 - a. Constipation or intestinal impaction or bezoar are potential complications, especially if multiple doses of charcoal are given.
 - b. Distension of the stomach with a potential risk of pulmonary aspiration.
 - c. Many commercially available charcoal products contain charcoal and the cathartic sorbitol in a premixed suspension. Even single doses of sorbitol often cause stomach cramps and vomiting, and repeated doses may cause serious fluid shifts to the intestine, diarrhea, dehydration, and hypernatremia, especially in young children and elderly persons.
 - d. May bind coadministered ipecac or acetylcysteine (not clinically significant).

TABLE I-37. DRUGS AND TOXINS POORLY ADSORBED BY ACTIVATED CHARCOAL^a

Alkali	Inorganic salts
Cyanide ^b	Iron
Ethanol and other alcohols	Lithium
Ethylene glycol	Mineral acids
Fluoride	Potassium
Heavy metals	

^aFew studies have been performed to determine in vivo adsorption of these and other toxins to activated charcoal. Adsorption may also depend on the specific type and concentration of charcoal.

^bCharcoal should still be given because usual doses of charcoal (60–100g) will adsorb usual lethal ingested doses of cyanide (200–300 mg).

4. Technique

- Give activated charcoal, 60–100 g (1 g/kg), PO or by gastric tube. If the quantity of an ingested substance is known, give at least 10 times the ingested dose of toxin by weight to prevent desorption of the toxin in the lower gastrointestinal tract.
- One or two additional doses of activated charcoal may be given at 1- or 2-hour intervals to ensure adequate gut decontamination, particularly after large ingestions. In rare cases, as many as 8 or 10 repeated doses may be needed to achieve a 10:1 ratio of charcoal to poison (eg, after an ingestion of 200 aspirin tablets); in such circumstances, the doses should be given over a period of several hours.

D. Cathartics. Controversy remains over the use of cathartics to hasten elimination of toxins from the gastrointestinal tract. Some toxicologists still use cathartics routinely when giving activated charcoal, even though little data exist to support their efficacy.

1. Indications

- To enhance gastrointestinal transit of the charcoal-toxin complex, decreasing the likelihood of desorption of toxin or development of a charcoal bezoar.
- To hasten passage of iron tablets and other ingestions not adsorbed by charcoal.

2. Contraindications

- Ileus or intestinal obstruction.
- Sodium- and magnesium-containing cathartics should not be used in patients with fluid overload or renal insufficiency, respectively.
- There is no role for oil-based cathartics (previously recommended for hydrocarbon poisoning).

3. Adverse effects

- Severe fluid loss, hypernatremia, and hyperosmolality may result from overuse or repeated doses of cathartics.
- Hypermagnesemia may occur in patients with renal insufficiency who are given magnesium-based cathartics.
- Abdominal cramping and vomiting may occur, especially with sorbitol.

4. Technique

- Administer the cathartic of choice (10% magnesium citrate, 3–4 mL/kg; or 70% sorbitol, 1–2 mL/kg) along with activated charcoal or mixed together as a slurry.
- Repeat with one-half the original dose if there is no charcoal stool after 6–8 hours.

E. Whole-bowel irrigation. Whole-bowel irrigation has become an accepted method for elimination of some drugs and poisons from the gut. The technique makes use of a surgical bowel-cleansing solution containing a nonabsorbable

polyethylene glycol in a balanced electrolyte solution, formulated to pass through the intestinal tract without being absorbed. This solution is given at high flow rates to force intestinal contents out by sheer volume.

1. Indications

- a. Large ingestions of iron, lithium, or other drugs poorly adsorbed to activated charcoal.
- b. Large ingestions of sustained-release or enteric-coated tablets containing valproic acid (eg, Depakote™), theophylline (eg, Theo-Dur™), aspirin (eg, Ecotrin™), verapamil (eg, Calan SR™), diltiazem (eg, Cardizem CD™), or other dangerous drugs.
- c. Ingestion of foreign bodies or drug-filled packets or condoms. While controversy persists about the optimal gut decontamination for “body stuffers” (persons who hastily ingest drug-containing packets to hide incriminating evidence), prudent management involves several hours of whole-bowel irrigation accompanied by activated charcoal. Follow-up imaging studies may be indicated to search for retained packets, if the amount of drug or its packaging is of concern.

2. Contraindications

- a. Ileus or intestinal obstruction.
- b. Obtunded, comatose, or convulsing patient unless the airway is protected.

3. Adverse effects

- a. Nausea and bloating.
- b. Regurgitation and pulmonary aspiration.
- c. Activated charcoal may not be as effective when given with whole-bowel irrigation.

4. Technique

- a. Administer bowel preparation solution (eg, CoLyte™ or GoLYTELY™), 2 L/h by gastric tube (children: 500 mL/h or 35 mL/kg/h), until rectal effluent is clear.
- b. Some toxicologists recommend administration of activated charcoal 25–50 g every 2–3 hours while whole-bowel irrigation is proceeding, if the ingested drug is adsorbed by charcoal.
- c. Be prepared for large-volume stool within 1–2 hours. Pass a rectal tube or, preferably, have the patient sit on a commode.
- d. Stop administration after 8–10 L (children: 150–200 mL/kg) if no rectal effluent has appeared.

F. Other oral binding agents. Other binding agents may be given in certain circumstances to trap toxins in the gut, although activated charcoal is the most widely used effective adsorbent. Table I–38 lists some alternative binding agents and the toxin(s) for which they may be useful.

TABLE I–38. SELECTED ORAL BINDING AGENTS

Drug or Toxin	Binding Agent(s)
Calcium	Cellulose sodium phosphate
Chlorinated hydrocarbons	Cholestyramine resin
Digitoxin ^a	Cholestyramine resin
Heavy metals (arsenic, mercury)	Demulcents (egg white, milk)
Iron	Sodium bicarbonate
Lithium	Sodium polystyrene sulfonate (Kayexalate)
Paraquat ^a	Fuller's earth, bentonite
Potassium	Sodium polystyrene sulfonate (Kayexalate)
Thallium	Prussian blue

^aActivated charcoal is also very effective.

G. Surgical removal. Occasionally, drug-filled packets or condoms, intact tablets, or tablet concretions persist despite aggressive gastric lavage or whole-gut lavage, and surgical removal may be necessary. Consult a regional poison control center or a medical toxicologist for advice.

Bond GR: The role of activated charcoal and gastric emptying in gastrointestinal decontamination: a state-of-the-art review. *Ann Emerg Med* 2002;39(3):273–286. [PMID: 11867980] (Review)

Tenenbein M: Position statement: whole bowel irrigation. American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists. *J Toxicol Clin Toxicol* 1997;35(7):753–762 [PMID: 9482429] (Although conclusive evidence is lacking, whole-bowel irrigation may be useful in various ingestions, including sustained-release products, iron, and drug packets.)

ENHANCED ELIMINATION

Measures to enhance elimination of drugs and toxins have been overemphasized in the past. Although a desirable goal, rapid elimination of most drugs and toxins is frequently not practical and may be unsafe. A logical understanding of pharmacokinetics as they apply to toxicology (toxicokinetics) is necessary for the appropriate use of enhanced removal procedures.

I. Assessment. Three critical questions must be answered:

A. Does the patient need enhanced removal? Ask the following questions. How is the patient doing? Will supportive care enable the patient to recover fully? Is there an antidote or other specific drug that might be used? Important indications for enhanced drug removal include the following:

1. Obviously severe or critical intoxication with a deteriorating condition despite maximal supportive care (eg, phenobarbital overdose with intractable hypotension).
2. The normal or usual route of elimination is impaired (eg, lithium overdose in a patient with renal failure).
3. The patient has ingested a known lethal dose or has a lethal blood level (eg, theophylline or methanol).
4. The patient has underlying medical problems that could increase the hazards of prolonged coma or other complications (eg, severe chronic obstructive pulmonary disease or congestive heart failure).

B. Is the drug or toxin accessible to the removal procedure? For a drug to be accessible to removal by extracorporeal procedures, it should be located primarily within the bloodstream or in the extracellular fluid. If it is extensively distributed to tissues, it is not likely to be easily removed.

1. The volume of distribution (Vd) is a numerical concept that provides an indication of the accessibility of the drug:

$$\begin{aligned} V_d &= \text{apparent volume into which the drug is distributed} \\ &= (\text{amount of drug in the body})/(\text{plasma concentration}) \\ &= (\text{mg/kg})/(\text{mg/L}) = \text{L/kg} \end{aligned}$$

A drug with a very large Vd has a very low plasma concentration. In contrast, a drug with a small Vd is potentially quite accessible by extracorporeal removal procedures. Table I–39 lists some common volumes of distribution.

2. Protein binding may affect accessibility; highly protein-bound drugs have low free drug concentrations and are difficult to remove by dialysis.

C. Will the method work? Does the removal procedure efficiently extract the toxin from the blood?

1. The clearance (CL) is the rate at which a given volume of fluid can be “cleared” of the substance.

TABLE I-39. VOLUME OF DISTRIBUTION OF SOME DRUGS AND POISONS

Large Vd (>5–10 L/kg)	Small Vd (<1 L/kg)
Antidepressants	Alcohols
Digoxin	Carbamazepine
Lindane	Lithium
Opiates	Phenobarbital
Phencyclidine (PCP)	Salicylate
Phenothiazines	Theophylline

- a. The CL may be calculated from the extraction ratio across the dialysis machine or hemoperfusion column, multiplied by the blood flow rate through the following system:

$$CL = \text{extraction ratio} \times \text{blood flow rate}$$

- b. A crude urinary CL measurement may be useful for estimating the effectiveness of fluid therapy for enhancing renal elimination of substances not secreted or absorbed by the renal tubule (eg, lithium):

$$\text{Renal CL} = \frac{\text{urine level} \times \text{urine flow rate}}{\text{serum level}}$$

Note: The units of clearance are milliliters per minute. Clearance is not the same as elimination rate (milligrams per minute). If the blood concentration is small, the actual amount of drug removed is also small.

- Total clearance** is the sum of all sources of clearance (eg, renal excretion plus hepatic metabolism plus respiratory and skin excretion plus dialysis). If the contribution of dialysis is small compared with the total clearance rate, then the procedure will contribute little to the overall elimination rate (Table I-40).
- The **half-life** ($T_{1/2}$) depends on the volume of distribution and the clearance:

$$T_{1/2} = \frac{0.693 \times Vd}{CL}$$

where the unit of measurement of Vd is liters (L) and of CL is liters per hour (L/h).

II. Methods available for enhanced elimination

- A. Urinary manipulation.** These methods require that the renal route be a significant contributor to total clearance.

- Forced diuresis may increase glomerular filtration rate, and ion trapping by urinary pH manipulation may enhance elimination of polar drugs.
- Alkalinization is commonly used for salicylate overdose, but “forced” diuresis (producing urine volumes of up to 1 L/h) is generally not used because of the risk of fluid overload.

- B. Hemodialysis.** Blood is taken from a large vein (usually a femoral vein) with a double-lumen catheter and is pumped through the hemodialysis system. The patient must be anticoagulated to prevent clotting of blood in the dialyzer. Drugs and toxins flow passively across the semipermeable membrane down a concentration gradient into a dialysate (electrolyte and buffer) solution. Fluid and electrolyte abnormalities can be corrected concurrently.

- Flow rates of up to 300–500 mL/min can be achieved, and clearance rates may reach 200–300 mL/min. Removal of drug is dependent on flow rate—insufficient flow (ie, due to clotting) will reduce clearance proportionately.

TABLE I-40. ELIMINATION OF SELECTED DRUGS AND TOXINS^a

Drug or Toxin	Volume of Distribution (L/kg)	Usual Body Clearance (mL/min)	Reported Clearance by:	
			Dialysis (mL/min)	Hemoperfusion ^b (mL/min)
Acetaminophen	0.8–1	400	120–150	125–300
Amitriptyline	6–10	500–800	NHD ^c	240 ^d
Bromide	0.7	5	100	NA ^c
Carbamazepine	1.2	60–90	14–59 ^e	80–130
Digitoxin	0.6	4	10–26	NA
Digoxin	5–7	150–200	NHD	90–140
Ethanol	0.7	100–300	100–200	NHP ^c
Ethchlorvynol	2–4	120–140	20–80	150–300 ^d
Ethylene glycol	0.6–0.8	200	100–200	NHP
Glutethimide	2.7	200	70	300 ^d
Isopropyl alcohol	0.7	30	100–200	NHP
Lithium	0.6–1	25–30	50–150	NHP
Meprobamate	0.75	60	60	85–150
Metformin			68–170	
Methanol	0.7	40–60	100–200	NHP
Formic acid (methanol metabolite)			198–248	
Methaqualone	5.8	130–175	23	150–270
Methotrexate	0.5–1	50–100	NA	54
Nadolol	2	135	46–102	NA
Nortriptyline	20–40	500–1000	24–34	216 ^d
Paraquat	2.8	30–200	10	50–155
Pentobarbital	0.8–1	27–36	23–55	200–300
Phenobarbital	0.8	2–15	60–75	100–300
Phenytoin	0.6	15–30	NHD	76–189
Procainamide	1.9	650	70	75
N-acetylprocainamide (NAPA)	1.4	220	48	75
Salicylate	0.15	30	35–80	57–116
Theophylline	0.3–0.6	80–120	30–50	60–225
Thiocyanate (cyanide metabolite)			83–102	
Trichloroethanol (chloral hydrate)	0.6–1.6	25	68–162	119–200
Valproic acid	0.15–0.4	10	23	55

^aAdapted in part from Pond SM: Diuresis, dialysis, and hemoperfusion: indications and benefits. *Emerg Med Clin North Am* 1984;2:29; and Cutler RE et al: Extracorporeal removal of drugs and poisons by hemodialysis and hemoperfusion. *Ann Rev Pharmacol Toxicol* 1987;27:169.

^bHemoperfusion data are mainly for charcoal hemoperfusion.

^cAbbreviations: NHD = not hemodialyzable; NA = not available; NHP = not hemoperfusible.

^dData are for XAD-4 resin hemoperfusion.

^eLower clearance reported with other dialysis equipment; newer high-flux dialysis may produce clearance of 59 mL/min up to estimated 100 mL/min (based on case reports).

2. Characteristics of the drug or toxin that enhance its extractability include small size (molecular weight < 500 daltons), water solubility, and low protein binding.
 3. **Note:** Smaller, portable dialysis units that utilize a resin column or filter to recycle a smaller volume of dialysate ("mini-dialysis") do not efficiently remove drugs or poisons and should not be used.
- C. Hemoperfusion.** Using equipment and vascular access similar to that for hemodialysis, the blood is pumped directly through a column containing an adsorbent material (either charcoal or Amberlite™ resin). Systemic anticoagulation is required, often in higher doses than for hemodialysis, and thrombocytopenia is a common complication.
1. Because the drug or toxin is in direct contact with the adsorbent material, drug size, water solubility, and protein binding are less important limiting factors.
 2. For most drugs, hemoperfusion can achieve greater clearance rates than hemodialysis. For example, the hemodialysis clearance rate for phenobarbital is 60–80 mL/min, whereas the hemoperfusion clearance rate is 200–300 mL/min.
- D. Peritoneal dialysis.** Dialysate fluid is infused into the peritoneal cavity through a transcutaneous catheter and drained off, and the procedure is repeated with fresh dialysate. The gut wall and peritoneal lining serve as the semipermeable membrane.
1. Peritoneal dialysis is easier to perform than hemodialysis or hemoperfusion and does not require anticoagulation, but it is only about 10–15% as effective owing to poor extraction ratios and slower flow rates (clearance rates 10–15 mL/min).
 2. However, peritoneal dialysis can be performed continuously, 24 hours a day; a 24-hour peritoneal dialysis with dialysate exchange every 1–2 hours is approximately equal to 4 hours of hemodialysis.
- E. Hemofiltration.** Continuous arteriovenous or venovenous hemodiafiltration (CAVHD or CVVHD, respectively) has been suggested as an alternative to conventional hemodialysis when the need for rapid removal of the drug is less urgent. Like peritoneal dialysis, these procedures are associated with lower clearance rates but have the advantage of being minimally invasive, with no significant impact on hemodynamics, and can be carried out "continuously" for many hours. However, their role in management of acute poisoning remains uncertain.
- F. Repeat-dose activated charcoal.** Repeated doses of activated charcoal (20–30 g or 0.5–1 g/kg every 2–3 hours) are given orally or via gastric tube. The presence of a slurry of activated charcoal throughout several meters of the intestinal lumen reduces blood concentrations by interrupting enterohepatic or enteroenteric recirculation of the drug or toxin, a mode of action quite distinct from simple adsorption of ingested but unabsorbed tablets. This technique is easy and noninvasive and has been shown to shorten the half-life of phenobarbital, theophylline, and several other drugs (Table I–41). However, it has not been shown in clinical trials to alter patient outcome. **Caution:** Repeat-dose charcoal may cause serious fluid and electrolyte disturbance secondary to large-volume diarrhea, especially if premixed charcoal-sorbitol suspensions are used. Also, it should not be used in patients with ileus or obstruction.

American Academy of Clinical Toxicology; European Association of Poisons Centres and Clinical Toxicologists: Position statement and practice guidelines on the use of multi-dose activated charcoal in the treatment of acute poisoning. *J Toxicol Clin Toxicol* 1999;37(6):731–751. [PMID: 10584586] (Although theoretically beneficial, this treatment has not yet been shown in a controlled study in poisoned patients to reduce morbidity or mortality.)

TABLE I-41. SOME DRUGS REMOVED BY REPEAT-DOSE ACTIVATED CHARCOAL^a

Caffeine	Phenobarbital
Carbamazepine	Phenylbutazone
Chlordecone	Phenytoin
Dapsone	Salicylate
Digitoxin	Theophylline
Nadolol	

^aNote: based on volunteer studies. There are few data on clinical benefit in drug overdose.

DISPOSITION OF THE PATIENT

I. Emergency department discharge or intensive care unit admission?

- A. All patients with potentially serious overdose should be observed for at least 6–8 hours before discharge or transfer to a nonmedical (eg, psychiatric) facility. If signs or symptoms of intoxication develop during this time, admission for further observation and treatment is required. **Caution:** Beware of delayed complications from slow absorption of medications (eg, from a tablet concretion or bezoar, or sustained-release or enteric-coated preparations). In these circumstances, a longer period of observation is warranted. If specific drug levels are determined, obtain repeated serum levels to be certain that they are decreasing as expected.
- B. Most patients admitted for poisoning or drug overdose will need observation in an intensive care unit, although this depends on the potential for serious cardiorespiratory complications. Any patient with suicidal intent must be kept under close observation.

II. Regional poison control center consultation: (800) 222-1222.

Consult with a regional poison control center to determine the need for further observation or admission, administration of antidotes or therapeutic drugs, selection of appropriate laboratory tests, or decisions about extracorporeal removal. An experienced clinical toxicologist is usually available for immediate consultation. A single toll-free number is now effective nationwide, and will automatically connect the caller to the regional poison control center.

III. Psychosocial evaluation

- A. **Psychiatric consultation for suicide risk.** All patients with intentional poisoning or drug overdose should have psychiatric evaluation for suicidal intent.
 1. It is not appropriate to discharge a potentially suicidal patient from the emergency department without a careful psychiatric evaluation. Most states have provisions for the physician to place an emergency psychiatric hold, forcing involuntary patients to remain under psychiatric observation for up to 72 hours.
 2. Patients calling from home after an intentional ingestion should always be referred to an emergency department for medical and psychiatric evaluation.
- B. **Child abuse (see also p 61) or sexual abuse**
 1. Children should be evaluated for the possibility that the ingestion was not accidental. Sometimes parents or other adults intentionally give children sedatives or tranquilizers to control their behavior.
 2. Accidental poisonings may also warrant social services referral. Occasionally children get into stimulants or other abused drugs that are left around the home. Repeated ingestions suggest overly casual or negligent parental behavior.
 3. Intentional overdose in a child or adolescent should raise the possibility of physical or sexual abuse. Teenage girls may have overdosed because of unwanted pregnancy.

IV. Overdose in the pregnant patient

- A. In general, it is prudent to check for pregnancy in any young woman with drug overdose or poisoning. Unwanted pregnancy may be a cause for intentional

- overdose, or special concerns may be raised about treatment of the pregnant patient.
- B. Inducing emesis with syrup of ipecac is probably safe in early pregnancy, but protracted vomiting is unwelcome, especially in the third trimester. Gastric lavage or oral activated charcoal is preferable in all trimesters.
 - C. Some toxins are known to be teratogenic or mutagenic (Table I-42). However, adverse effects on the fetus are generally associated with chronic, repeated use as opposed to acute, single exposure.

Lemke T, Wang R: Emergency department observation for toxicologic exposures. *Emerg Med Clin North Am* 2001;19(1):155-167, viii. [PMID: 11214396] (Criteria for admission and discharge vary with the exposure, and Observation Unit admission may be appropriate for some patients.)

► **SPECIAL CONSIDERATIONS IN PEDIATRIC PATIENTS**

Delia A. Dempsey, MD, MS

The majority of calls to poison control centers involve children under 5 years of age. Fortunately, children account for a minority of serious poisonings requiring emergency hospital treatment. Most common childhood ingestions involve nontoxic substances or nontoxic doses of potentially toxic drugs or products (see p 286). The leading causes of serious or fatal childhood poisoning include iron supplements (p 230); tricyclic antidepressants (p 90); cardiovascular medications such as digitalis (p 155), beta blockers (p 131), or calcium antagonists (p 144); methylsalicylate (p 331); and hydrocarbons (p 219). See Table I-43.

- I. **High-risk populations.** Two age groups are commonly involved in pediatric poisonings: children between 1 and 5 years old and adolescents.
- A. **Ingestions in toddlers and young children** usually result from oral exploration. Unintentional ingestion in children under 6 months of age or between the ages of 5 and adolescence is rare. In young infants, consider the possibility of intentional administration by an older child or adult. In school-age chil-

TABLE I-43. EXAMPLES OF POTENT PEDIATRIC POISONS

Drug or Poison	Potentially Fatal Dose in a 10-kg Toddler	No. of Pediatric Deaths Reported to AAPCC 1983-1990
Benzocaine	2 mL of a 10% gel	
Camphor	5 mL of 20% oil	
Chloroquine	One 500-mg tablet	2
Chlorpromazine	One or two 200-mg tablets	1
Codeine	Three 60-mg tablets	
Desipramine	Two 75-mg tablets	4
Diphenoxylate/Atropine (Lomotil)	Five 2.5-mg tablets	2
Hydrocarbons (eg, kerosene)	One swallow (if aspirated)	12
Hypoglycemic sulfonylureas	Two 5-mg glyburide tablets	
Imipramine	One 150-mg tablet	3
Iron	Ten adult-strength tablets	16
Lindane	Two teaspoons (10 mL)	
Methyl salicylate	Less than 5 mL of oil of wintergreen	4
Quinidine	Two 300-mg tablets	1
Selenious acid (gun bluing)	One swallow	4
Theophylline	One 500-mg tablet	
Thioridazine	One 200-mg tablet	
Verapamil	One or two 240-mg tablets	3

dren, suspect abuse or neglect as a reason for the ingestion, and in adolescents, suspect a suicide attempt.

- B. In adolescents and young adults**, overdoses are usually suicidal but may also result from drug abuse or experimentation. Common underlying reasons for adolescents' suicide attempts include pregnancy; sexual, physical, or mental abuse; school failure; conflict with peers; conflict with homosexual orientation; a sudden or severe loss; and alcoholism or illicit drug use. Any adolescent who makes a suicide attempt or gesture needs psychiatric evaluation and follow-up.
- II. Poisoning prevention.** Young children with an unintentional ingestion are at higher risk for a second ingestion than the general pediatric population. After an incident, prevention strategies need to be reviewed. If the family does not understand the instructions or it is the second poisoning incident, consider a home evaluation for childproofing by a public health nurse or other health-care professional.
 - A. Childproof** the home, day-care setting, and households the child commonly visits (eg, grandparents and other relatives). Store medicines, chemicals, and cleaning products out of the reach of children or in locked cabinets. Do not store chemicals in food containers, and do not store chemicals in the same cabinets as food. Common places children find medications include visitors' purses or backpacks and bedside tables.
 - B. Use child-resistant containers** to store prescription and nonprescription medications. However, child-resistant containers are not childproof; they only slow down the time it takes a determined child to get into the container.

- III. Child abuse.** Consider the possibility that the child was intentionally given the drug or toxin. Most states require that all health-care professionals report suspected cases of child abuse or neglect, which means that it is not a discretionary decision but a **legal obligation to report any suspicious incident**. The parents or guardians should be informed in a straightforward, nonjudgmental manner that a report is being made under this legal obligation. In serious cases, the suspected abuse report should be made before the child is released, and the local child-protective services should decide whether it is safe to release the child to the parents or guardians. In unclear situations, the child can be admitted for “observation” to allow time for social services to make an expeditious evaluation. The following should alert medical personnel to the possibility of abuse or neglect:
- A.** The story does not make sense or does not ring true, or it changes over time, or different people give different stories.
 - B.** The child is nonambulatory (eg, child under 6 months of age). Carefully review how the child gained access to the drug or toxin.
 - C.** The child is over 4–5 years old. Accidental ingestions are rare in older children, and ingestion may be a signal of abuse or neglect.
 - D.** The drug ingested was a tranquilizer (eg, haloperidol or chlorpromazine), a drug of abuse (eg, cocaine or heroin), a sedative (eg, diazepam), or ethanol, or the parents are intoxicated.
 - E.** There is a long interval between the time of ingestion and the time the child is taken for medical evaluation.
 - F.** There are signs of physical or sexual abuse or neglect: multiple or unusual bruises; a broken bone or burns; a very dirty, unkempt child; or a child with a flat affect or indifferent or inappropriate behavior.
 - G.** A history of repeated episodes of possible or documented poisonings or a history of prior abuse.
 - H.** Munchausen syndrome by proxy: drugs or toxins are given to the child to simulate illness. Most perpetrators are mothers, often with some medical background. This is a rare diagnosis.
- IV. Clinical evaluation.** The physical and laboratory evaluation is essentially the same as for adults. However, normal vital signs vary with age (Table I–44).

TABLE I–44. PEDIATRIC VITAL SIGNS^a

Age	Respiratory Rate (min)	Heart Rate (min)	Blood Pressure (mm Hg)			
			Lower Limit	Average	Upper Limit	Severe
Newborn	30–80	110–190	52/25	50–55 ^b	95/72	110/85
1 month	30–50	100–170	64/30	85/50	105/68	120/85
6 months	30–50	100–170	60/40	90/55	110/72	125/85
1 year	20–40	100–160	66/40	90/55	110/72	125/88
2 years	20–30	100–160	74/40	90/55	110/72	125/88
4 years	20–25	80–130	79/45	95/55	112/75	128/88
8 years	15–25	70–110	85/48	100/60	118/75	135/92
12 years	15–20	60–100	95/50	108/65	125/84	142/95

^bMean arterial pressure range on the first day of life.

- A. Heart rate.** Newborns may have normal heart rates as high as 190/min, and 2-year-olds up to 120/min. Abnormal tachycardia or bradycardia suggests the possibility of hypoxemia, in addition to the numerous drugs and poisons that affect heart rate and rhythm (see Tables I-4 through I-7).
- B. Blood pressure** is a very important vital sign in a poisoned child. The blood pressure cuff must be of the proper size; cuffs that are too small can falsely elevate the pressure. The blood pressures of infants are difficult to obtain by auscultation but are easily obtained by Doppler.
1. Many children normally have a lower blood pressure than adults. However, low blood pressure in the context of a poisoning should be regarded as normal only if the child is alert, active, appropriate, and has normal peripheral perfusion.
 2. Idiopathic or essential hypertension is rare in children. Elevated blood pressure should be assumed to indicate an acute condition, although the systolic blood pressure can be transiently elevated if the child is vigorously crying or screaming. Unless a child's baseline blood pressure is known, values at the upper limit of normal should be assumed to be "elevated." The decision to treat elevated blood pressure must be made on an individual basis, based on the clinical scenario and the toxin involved.
- V. Neonates** present specific problems, including unique pharmacokinetics and potentially severe withdrawal from prenatal drug exposure.
- A. Neonatal pharmacokinetics.** The newborn (birth to 1 month) and infants (1-12 months) are unique from a toxicologic and pharmacologic perspective. Drug absorption, distribution, and elimination are different from those of older children and adults. Incorrect dosing, transplacental passage proximate to the time of birth, breast-feeding, dermal absorption, and intentional poisoning are potential routes of toxic exposure. Of particular importance are enhanced skin absorption and reduced drug elimination, which may lead to toxicity after relatively mild exposure.
1. **Skin absorption.** Neonates have a very high surface area to body weight, which predisposes them to poisoning via percutaneous absorption (eg, hexachlorophene, boric acid, or alcohols).
 2. **Elimination** of many drugs (eg, acetaminophen, many antibiotics, caffeine, lidocaine, morphine, phenytoin, and theophylline) is prolonged in neonates. For example, the half-life of caffeine is approximately 3 hours in adults but may be greater than 100 hours in newborns.
- B. Neonatal drug withdrawal** may occur in infants with chronic prenatal exposure to illicit or therapeutic drugs. The onset is usually within 72 hours of birth, but a postnatal onset as late as 14 days has been reported. Signs usually commence in the nursery, and infants are not discharged until clinically stable. However, with early discharge from nurseries becoming the norm, an infant in withdrawal may first present to an emergency department or acute care clinic. The presentation may be as mild as colic or severe as withdrawal seizures or profound diarrhea.
1. **Opioids** (especially methadone and heroin) are the most common cause of serious neonatal drug withdrawal symptoms. Other drugs for which a withdrawal syndrome has been reported include phencyclidine (PCP), cocaine, amphetamines, tricyclic antidepressants, phenothiazines, benzodiazepines, barbiturates, ethanol, clonidine, diphenhydramine, lithium, meprobamate, and theophylline. A careful drug history from the mother should include illicit drugs, alcohol, and prescription and over-the-counter medications, and whether she is breast-feeding.
 2. **The manifestations of neonatal opioid withdrawal** include inability to sleep, irritability, tremulousness, inconsolability, high-pitched incessant cry, hypertonia, hyperreflexia, sneezing and yawning, lacrimation, disorganized suck, poor feeding, vomiting, diarrhea, tachypnea or respiratory distress, tachycardia, autonomic dysfunction, sweating, fevers, and seizures. Morbidity and mortality from untreated opioid withdrawal can be significant

and commonly result from weight loss, metabolic acidosis, respiratory alkalosis, dehydration, electrolyte imbalance, and seizures. Withdrawal is a diagnosis of exclusion; immediately rule out sepsis, hypoglycemia, hypocalcemia, and hypoxia, and consider hyperbilirubinemia, hypomagnesemia, hyperthyroidism, and intracranial hemorrhage. Seizures do not usually occur as the only clinical manifestation of opioid withdrawal.

3. **Treatment of neonatal opioid withdrawal** is mainly supportive and includes swaddling, rocking, a quiet room, frequent small feedings with high-caloric formula, and intravenous fluids if necessary. A variety of drugs have been used, including morphine, paregoric, tincture of opium, diazepam, lorazepam, chlorpromazine, and phenobarbital. Numerous abstinence-scoring systems exist to objectively evaluate and treat opioid withdrawal. The scoring and treatment of a neonate in withdrawal should be supervised by a neonatologist or a pediatrician experienced with neonatal withdrawal.

► SPECIAL CONSIDERATIONS IN THE EVALUATION OF DRUG-FACILITATED ASSAULT

Jo Ellen Dyer, PharmD

Since 1996, reports of drug-facilitated assault have been increasing. Drugs may be used to render the victim helpless or unconscious so that the assailant can commit a rape or robbery. The amnestic effects of many of the drugs used often leave little or no recollection of the events, making investigation and prosecution of the suspect more difficult.

- I. **High-risk populations** include single women or men, traveling or new to an area, without companions. Drug administration may occur in a bar or club, when the victim visits the restroom or accepts an opened bottle or drink. In one series of self-reported cases half of the victims reported meeting the assailant in a public place and over 70% of the victims knew the assailant (eg, a friend or colleague).
- II. **Drugs utilized.** Contrary to the popular belief that specific "date rape drugs" are involved in these crimes, a variety of drugs with amnestic or CNS depressant effects can be used to facilitate assault, including benzodiazepines, other sedative-hypnotic drugs, skeletal muscle relaxants, anticholinergics, hallucinogens, and of course, ethanol (Table I-45).
 - A. Note that many of these drugs are also commonly used to "get high" and might have been self-administered by the victim for this purpose.
 - B. Benzodiazepines are often selected for their anterograde amnestic effect, which is related to but distinct from sedation. The strength of amnestic effects can be predicted to increase with dose, rapidity of onset, lipophilic character, and slow redistribution from the CNS.
- III. **Routes of surreptitious drug administration:**
 - A. Drink: tablet, ice, liquid in eyedropper.
 - B. Smoke: applied to a cigarette or joint.
 - C. Ingestion: brownie, gelatin, fruit.
 - D. Vaginal syringe: drug in contraceptive gel.
 - E. Represented as another drug.
- IV. **Clinical evaluation.** If the victim presents early after the assault, he or she may still be under the influence of the drug and may appear inappropriately disinhibited or relaxed for the situation. Unfortunately, victims often present many hours, days, or even weeks after the assault, making collection of physical and bio-

TABLE I-45. EXAMPLES OF SUBSTANCES DETECTED IN URINE OF DRUG-FACILITATED ASSAULT VICTIMS

Drug	Usual Duration of Detection in Urine ^a
Amphetamines	1–3 days
Barbiturates	2–7 days
Benzodiazepines	2–7 days
Benzoylcegonine	1–2 days
Cannabinoids	2–5 days (single use)
Carisoprodol	1–2 days ^b
Chloral hydrate	1–2 days ^b
Clonidine	1–2 days ^b
Cyclobenzaprine	1–2 days ^b
Diphenhydramine	1–2 days ^b
Ethanol	Less than 1 day
Gamma hydroxybutyrate, GHB	Less than 1 day ^b
Ketamine	1–2 days ^b
Meprobamate	1–2 days ^b
Opioids	2–3 days
Scopolamine	1–2 days ^b

^aEstimate of the duration of detection, using methods more sensitive than typical drug screening. Actual detection will depend on individual metabolism, dose, and concentration in specimen. Also, assays vary in sensitivity and specificity depending on the laboratory, so it is important consult with the lab for definitive information.

^bSpecific information not available; duration given is an estimate.

chemical evidence much more difficult. Determining the time course of drug effects with estimation of last memory and first recall may provide useful information to investigators.

- A. **Use open-ended questions** to avoid suggesting symptoms to a victim who may be trying to fill in a lapse in memory.
 - B. Perform a thorough examination and maintain the legal chain of custody for any specimens obtained.
- V. **Laboratory.** Timing of laboratory analysis may be crucial, as elimination rates of commonly used sedative and amnestic drugs vary and some may be extremely short. Immediate collection of toxicology specimens is important to avoid loss of evidence. For a service that deals in assaults or sexual abuse, it is important to confer in advance with the laboratory, so that it is clearly understood what type of testing will be performed; the laboratory can then develop a testing strategy (what tests to use, the sequence of tests and confirmations, and level of sensitivity and specificity). Such a service should ideally be part of a law enforcement agency.
- A. **Blood.** Collect a specimen as soon as possible and within 24 hours of alleged assault. Have the specimen centrifuged and the plasma or serum frozen at -80°C for future analysis. Pharmacokinetic evaluation of multiple blood levels may allow estimations of time course, level of consciousness, and amount ingested.
 - B. **Urine.** Collect a specimen if it is within 72 hours of suspected ingestion and freeze for analysis. (**Note:** flunitrazepam [Rohypnol™] may be detected for up 96 hours.)
 - C. **Analysis.** (See Table I-45.) Hospital laboratories doing routine toxicology testing have different testing strategies and levels of detection, and may not

detect drugs used to facilitate sexual assault. Rapid toxicology screens (eg, "drugs of abuse" screens) *will not detect* all commonly available benzodiazepines or other CNS depressants (such as ketamine, gamma-hydroxybutyrate, or carisoprodol) that are popular drugs of abuse. It may be necessary to contract for special services through national reference laboratories, state laboratories, or a local medical examiner's office to identify less common drugs used for assault and to detect very low levels of drugs that remain in cases of late presentation.

VI. Treatment of the intoxication is based on the clinical effects of the drug(s) involved. Assessment and treatment of effects related to individual drugs is detailed in Section II of this book. In addition, victims often need psychological support and counseling, and the involvement of law enforcement authorities. If the assault involves a minor, state law generally mandates reporting to child protective services and law enforcement officials.

SECTION II. Specific Poisons and Drugs: Diagnosis and Treatment

► ACETAMINOPHEN

Kent R. Olson, MD

Acetaminophen (Anacin-3, Liquiprin, Panadol, Paracetamol, Temptra, Tylenol, and many other brands) is a widely used drug found in many over-the-counter and prescription analgesics and cold remedies. When it is combined with another drug such as codeine or propoxyphene, the more dramatic acute symptoms caused by the other drug may mask the mild and nonspecific symptoms of early acetaminophen toxicity, resulting in missed diagnosis or delayed antidotal treatment. Common combination products containing acetaminophen include Darvocet, Excedrin ES, Nyquil, Percocet, Unisom Dual Relief Formula, Sominex 2, Tylenol with Codeine, Tylox, Vicks Formula 44-D, and Vicodin.

I. Mechanism of toxicity

- A. **Hepatic injury.** One of the products of normal metabolism of acetaminophen by cytochrome P-450 mixed-function oxidase enzymes is highly toxic; normally this reactive metabolite (NAPQI) is rapidly detoxified by glutathione in liver cells. However, in an overdose, production of NAPQI exceeds glutathione capacity and the metabolite reacts directly with hepatic macromolecules, causing liver injury.
- B. **Renal damage** may occur by the same mechanism, owing to renal P-450 metabolism.
- C. Overdose during **pregnancy** has been associated with fetal death and spontaneous abortion.
- D. **Pharmacokinetics.** Rapidly absorbed, with peak levels usually reached within 30–120 min (**Note:** absorption may be delayed after ingestion of sustained-release products or with co-ingestion of opioids or anticholinergics). Volume of distribution (Vd) = 0.8–1 L/kg. Eliminated by liver conjugation (90%) to nontoxic glucuronides or sulfates, cytochrome P-450 mixed-function oxidase accounts for only about 3–8% but produces a toxic intermediate (see A, above). The elimination half-life is 1–3 hours after therapeutic dose and may be greater than 12 hours after overdose. (See also Table II–59, p 381.)

II. Toxic dose

- A. **Acute ingestion** of more than 150–200 mg/kg in children or 6–7 g in adults is potentially hepatotoxic.
 1. Children younger than 10–12 years of age appear to be less susceptible to hepatotoxicity because of the smaller contribution of cytochrome P-450 to acetaminophen metabolism.
 2. On the other hand, the margin of safety is lower in patients with induced cytochrome P-450 microsomal enzymes, because more of the toxic metabolite may be produced. **High-risk patients** include alcoholics and patients taking anticonvulsant medications or isoniazid. Fasting and malnutrition also increase the risk of hepatotoxicity, presumably by lowering cellular glutathione stores.
- B. **Chronic toxicity** has been reported after daily consumption of supratherapeutic doses (more than 4–6 g/day) by alcoholic patients. Children have developed toxicity after receiving as little as 60–150 mg/kg/day for 2–8 days.

III. Clinical presentation.

Clinical manifestations depend on the time after ingestion.

- A. **Early** after acute acetaminophen overdose, there are usually no symptoms other than anorexia, nausea, or vomiting. Rarely, a massive overdose may cause altered mental status and metabolic acidosis.

B. After 24–48 hours, when transaminase levels (AST and ALT) begin to rise, hepatic necrosis becomes evident. If acute fulminant hepatic failure occurs, death may ensue. Encephalopathy, metabolic acidosis, and a continuing rise in the prothrombin time (PT) indicate a poor prognosis. Acute renal failure occasionally occurs, with or without concomitant liver failure.

IV. Diagnosis. Prompt diagnosis is possible only if the ingestion is suspected and a serum acetaminophen level is obtained. However, patients may fail to provide the history of acetaminophen ingestion, because they are unable (eg, comatose from another ingestion), unwilling, or unaware of its importance. Therefore, many clinicians routinely order acetaminophen levels in all overdose patients, regardless of the history of substances ingested.

A. Specific levels

1. After an **acute overdose**, obtain a 4-hour postingestion acetaminophen level and use the nomogram (Figure II–1) to predict the likelihood of toxic-

FIGURE II–1. Nomogram for prediction of acetaminophen hepatotoxicity after acute overdose. The upper line defines serum acetaminophen concentrations likely to be associated with hepatotoxicity; the lower line defines serum levels 25% below those expected to cause hepatotoxicity. (Courtesy of McNeil Consumer Products, Inc.)

ity. Do not attempt to interpret a level drawn before 4 hours, unless it is "nondetectable." Obtain a second level at 8 hours if the 4-hour value is borderline or if delayed absorption is anticipated.

2. The nomogram should not be used to assess chronic or repeated ingestions.
3. Falsely elevated acetaminophen levels may occur in the presence of high levels of salicylate and other interferents by certain methods (see Table I-33, p 43).

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver transaminases, and prothrombin time.

V. Treatment

A. Emergency and supportive measures

1. **Spontaneous vomiting** may delay the administration of antidote or charcoal (see below) and should be treated with metoclopramide (see p 467) or ondansetron (p 481).
2. Provide general supportive care for hepatic or renal failure if it occurs. Emergency **liver transplant** may be necessary for fulminant hepatic failure. Encephalopathy, metabolic acidosis, hypoglycemia, and progressive rise in the prothrombin time are indications of severe liver injury.

B. Specific drugs and antidotes. If the serum level falls above the upper ("probable toxicity") line on the nomogram or if stat serum levels are not immediately available, initiate antidotal therapy with **N-acetylcysteine** (NAC, Mucomyst, p 405), with a loading dose of 140 mg/kg orally. The effectiveness of NAC depends on **early treatment**, before the metabolite accumulates; it is of maximal benefit if started within 8–10 hours and of diminishing value after 12–16 hours (however, treatment should not be withheld, even if the delay is 24 hours or more). If vomiting interferes with oral acetylcysteine administration, give it by gastric tube and use high-dose metoclopramide (1–2 mg/kg intravenously [IV]; see p 467) or ondansetron (p 481), or give the NAC intravenously (p 405) if necessary.

1. If the serum level falls between the two nomogram lines, consider giving NAC if the patient is at increased risk for toxicity; eg, the patient is alcoholic, malnourished or fasting, or taking drugs that induce P-450 2E1 activity (eg, INH); after multiple or subacute overdoses; or if the time of ingestion is uncertain or unreliable.
2. If the serum level falls below the lower nomogram line, treatment is not indicated unless the time of ingestion is uncertain or the patient is considered to be at particularly high risk.
3. **Note:** After ingestion of **extended-release** tablets (eg, Tylenol Arthritis Pain™), which are designed for prolonged absorption, there may be a delay before the peak acetaminophen level is reached. This can also occur after co-ingestion of drugs that delay gastric emptying, such as opioids or anticholinergics. In such circumstances, repeat the serum acetaminophen level at 8 hours and possibly 12 hours.
4. **Duration of NAC treatment.** The current widely used US protocol for treatment of acetaminophen poisoning calls for 17 doses of oral NAC given over approximately 72 hours. However, successful protocols in Canada, the United Kingdom, and Europe utilize intravenous NAC for only 20 hours. We give NAC orally until 36 hours have passed since the time of ingestion. Then, if the serum acetaminophen level is below the limits of detection and liver transaminase levels are normal, NAC can be stopped. If there is evidence of hepatic toxicity, then NAC should be continued until liver function tests are improving.
5. **Chronic acetaminophen ingestions:** patients may give a history of several doses taken over 24 hours or more, in which case the nomogram cannot accurately estimate the risk of hepatotoxicity. In such cases, we advise NAC treatment if the amount ingested was more than 150–200 mg/kg or 6–7 g

within a 24-hour period, or if liver enzymes are elevated, or if the patient falls within a high-risk group (see above). Treatment may be stopped 36 hours after the last dose of acetaminophen if the liver enzymes are normal.

C. Decontamination (see p 47)

- 1. Prehospital.** Administer activated charcoal. If charcoal is not readily available and a delay of more than 60 minutes is expected before it can be given, consider using ipecac to induce vomiting, if it can be given within a few minutes of exposure.
- 2. Hospital.** Administer activated charcoal. Although activated charcoal adsorbs some of the orally administered antidote *N*-acetylcysteine, this effect is not considered clinically important. Gastric emptying is not necessary if charcoal can be given promptly. Do not administer charcoal if more than 3–4 hours have passed since ingestion, unless delayed absorption is suspected (eg, as with Tylenol Arthritis Pain™ or co-ingestants containing opioids or anticholinergic agents).

D. Enhanced elimination. Hemoperfusion effectively removes acetaminophen from the blood, but is not generally indicated because antidotal therapy is so effective.

Boutis K, Shannon M: Nephrotoxicity after acute severe acetaminophen poisoning in adolescents. *J Toxicol Clin Toxicol* 2001;39(5):441–445. [PMID: 11545233] (Nephrotoxicity occurred in about 9% of adolescents with severe acetaminophen poisoning.)

Brok J et al: Interventions for paracetamol (acetaminophen) overdoses. *Cochrane Database Syst Rev* 2002;(3):CD003328. [PMID: 12137690] (There are few randomized controlled trials of treatment, but oral activated charcoal and use of *N*-acetylcysteine is recommended, with no NAC regimen proven more effective than any other.)

► AMANTADINE

Kent R. Olson, MD

Amantadine (Symmetrel) is an antiviral agent that is also effective in the treatment of Parkinson's disease and for prophylaxis against the parkinsonian side effects of neuroleptic agents. Although there is limited information about its effects in acute overdose, it has been associated with seizures, arrhythmias, neuroleptic malignant syndrome, and death.

I. Mechanism of toxicity

A. Amantadine is thought to both enhance the release of dopamine and prevent dopamine reuptake in the peripheral and central nervous systems. In addition, it has anticholinergic properties, especially in overdose.

B. Pharmacokinetics. Peak absorption = 1–4 hours; volume of distribution (Vd) = 4–8 L/kg. Eliminated renally with a half-life of 7–37 hours (see also Table II–59).

II. Toxic dose. The toxic dose has not been determined. Because the elimination of amantadine depends entirely on kidney function, elderly patients with renal insufficiency may develop intoxication with therapeutic doses.

III. Clinical presentation

A. Amantadine intoxication causes agitation, visual hallucinations, nightmares, disorientation, delirium, slurred speech, ataxia, myoclonus, tremor, and sometimes seizures. Anticholinergic manifestations include dry mouth, urinary retention, and mydriasis. Rarely, ventricular arrhythmias including torsade de pointes (see p 14) and multifocal premature ventricular contractions may occur. Amantadine has also been reported to cause heart failure.

B. Amantadine withdrawal, either after standard therapeutic use or in the days following an acute overdose, may result in hyperthermia and rigidity (similar to neuroleptic malignant syndrome; see p 21).

IV. Diagnosis is based on a history of acute ingestion or is made by noting the above-mentioned constellation of symptoms and signs in a patient taking amantadine.

- A. Specific levels** are not readily available. Serum levels above 1.5 mg/L have been associated with toxicity.
- B. Other useful laboratory studies** include electrolytes, BUN, creatinine, CPK, and ECG.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), arrhythmias (p 13), and hyperthermia (p 21) if they occur.
3. Monitor the asymptomatic patient for at least 8–12 hours after acute ingestion.

B. Specific drugs and antidotes. There is no known antidote. Although some of the manifestations of toxicity are caused by the anticholinergic effects of amantadine, physostigmine should not be used.

1. Treat **tachyarrhythmias** with beta blockers such as propranolol (see p 496) or esmolol (p 443).
2. **Hyperthermia** requires urgent cooling measures (see p 21) and may respond to specific pharmacologic therapy with dantrolene (p 431). When hyperthermia occurs in the setting of amantadine withdrawal, some have advocated using amantadine as therapy.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. Amantadine is not effectively removed by dialysis, because the volume of distribution is very large (5 L/kg). The serum elimination half-life ranges from 12 hours to 34 days, depending on renal function. In a patient with no renal function, dialysis or hemoperfusion may be necessary.

Yang CC, Deng JF: Anticholinergic syndrome with severe rhabdomyolysis—an unusual feature of amantadine toxicity. *Intensive Care Med* 1997;23(3):355–356. [PMID: 9083247] (Case report.)

► AMMONIA

R. Steven Tharratt, MD

Ammonia is widely used as a refrigerant, a fertilizer, and a household and commercial cleaning agent. Anhydrous ammonia (NH_3) is a highly irritating gas that is very water-soluble. Aqueous solutions of ammonia may be strongly alkaline, depending on the concentration. Solutions for household use are usually 5–10% ammonia, but commercial solutions may be 25–30% or more. The addition of ammonia to chlorine or hypochlorite solutions will produce chloramine gas, an irritant with properties similar to those of chlorine (see p 162).

I. Mechanism of toxicity. Ammonia gas is highly water-soluble and rapidly produces an alkaline corrosive effect on contact with moist tissues such as the eyes and upper respiratory tract. Exposure to aqueous solutions causes corrosive alkaline injury to the eyes, skin, or gastrointestinal tract (see Caustic and Corrosive Agents, p 157).

II. Toxic dose

A. Ammonia gas. The odor of ammonia is detectable at 3–5 ppm, and persons without protective gear will experience respiratory irritation at 50 ppm and will usually self-evacuate the area. Eye irritation is common at 100 ppm. The workplace recommended exposure limit (ACGIH TLV-TWA) for anhydrous

ammonia gas is 25 ppm as an 8-hour time-weighted average. The level considered immediately dangerous to life or health (IDLH) is 300 ppm.

- B. Aqueous solutions.** Diluted aqueous solutions of ammonia (eg, < 5%) rarely cause serious burns but are moderately irritating. More concentrated industrial cleaners (eg, 25–30% ammonia) are much more likely to cause serious corrosive injury.

III. Clinical presentation. Clinical manifestations depend on physical state and route of exposure.

- A. Inhalation of ammonia gas.** Symptoms are rapid in onset owing to the high water-solubility of ammonia and include immediate burning of the eyes, nose, and throat, accompanied by coughing. With serious exposure, upper-airway swelling may rapidly cause airway obstruction, preceded by croupy cough, hoarseness, and stridor. Bronchospasm with wheezing may occur. Massive inhalational exposure may cause noncardiogenic pulmonary edema.

- B. Ingestion of aqueous solutions.** Immediate burning in the mouth and throat is common. With more concentrated solutions, serious esophageal and gastric burns are possible, and victims may have dysphagia, drooling, and severe throat, chest, and abdominal pain. Hematemesis and perforation of the esophagus or stomach may occur. The absence of oral burns does not rule out significant esophageal or gastric injury.

- C. Skin or eye contact with gas or solution.** Serious alkaline corrosive burns may occur.

IV. Diagnosis is based on a history of exposure and description of the typical ammonia smell, accompanied by typical irritative or corrosive effects on the eyes, skin, and upper respiratory or gastrointestinal tract.

- A. Specific levels.** Blood ammonia levels may be elevated (normal 8–33 micromol/L) but are not predictive of toxicity.

- B. Other useful laboratory studies** include electrolytes, arterial blood gases or pulse oximetry, chest x-ray, and pH paper test strips.

V. Treatment

- A. Emergency and supportive measures.** Treatment depends on the physical state of the ammonia and the route of exposure.

1. Inhalation of ammonia gas

- Observe carefully for signs of progressive upper-airway obstruction, and intubate early if necessary (see p 4).
- Administer humidified supplemental oxygen and bronchodilators for wheezing (see p 8). Treat noncardiogenic pulmonary edema (p 7) if it occurs.
- Asymptomatic or mildly symptomatic patients may be sent home after a brief (1–2-hour) observation.

- 2. Ingestion of aqueous solution.** If a solution of 10% or greater has been ingested or if there are any symptoms of corrosive injury (dysphagia, drooling, or pain), perform flexible endoscopy to evaluate for serious esophageal or gastric injury. Obtain a chest x-ray to look for mediastinal air, which suggests esophageal perforation.

- 3. Eye exposure.** After eye irrigation, perform fluorescein examination and refer the patient to an ophthalmologist if there is evidence of corneal injury.

- B. Specific drugs and antidotes.** There is no specific antidote for these or other common caustic burns. The use of corticosteroids in alkaline corrosive ingestions has been proved ineffective and may be harmful in patients with perforation or serious infection.

C. Decontamination (see p 46)

- 1. Inhalation.** Remove immediately from exposure, and give supplemental oxygen if available.

2. Ingestion

- a. Prehospital.** Immediately give water by mouth to dilute the ammonia. Do **not** induce vomiting, as this may aggravate corrosive effects. Do **not** attempt to neutralize the ammonia (eg, with an acidic solution).

- b. **Hospital.** Gastric lavage may be useful to remove liquid caustic in the stomach and to prepare for endoscopy; use a small, flexible tube and pass gently to avoid injury to damaged mucosa.
- c. Do **not** use activated charcoal; it does not adsorb ammonia, and it may obscure the endoscopist's view.
- 3. **Skin and eyes.** Remove contaminated clothing and wash exposed skin with water. Irrigate exposed eyes with copious amounts of tepid water or saline (see p 47).
- D. **Enhanced elimination.** There is no role for dialysis or other enhanced elimination procedures.

► AMPHETAMINES

Timothy E. Albertson, MD, PhD

Dextroamphetamine (Dexedrine) and methylphenidate (Ritalin) are used for the treatment of narcolepsy and for attention-deficit disorders in children. Several amphetaminelike drugs (benzphetamine, diethylpropion, phendimetrazine, phenmetrazine, and phentermine) are marketed as prescription anorectic medications for use in weight reduction (Table II-1). Fenfluramine and dexfenfluramine were marketed as anorectic medications but were withdrawn from the market in 1997 because of concerns about cardiopulmonary toxicity with long-term use. Methamphetamine (crank, speed), 3,4-methylenedioxymethamphetamine (MDMA, ecstasy), and several other amphetamine derivatives (see Lysergic Acid Diethylamide [LSD] and Other Hallucinogens, p 247), as well as a number of prescription drugs, are used orally and intravenously as illicit stimulants. "Ice" is a smokable form of methamphetamine. Phenylpropanolamine, ephedrine, and other over-the-counter decongestants are discussed on p 320.

I. Mechanism of toxicity

- A. Amphetamine and related drugs activate the sympathetic nervous system via central nervous system (CNS) stimulation, peripheral release of catecholamines, inhibition of neuronal reuptake of catecholamines, and inhibition of monoamine oxidase. Fenfluramine and dexfenfluramine cause serotonin release and block neuronal serotonin uptake. The various drugs have different profiles of action resulting in different levels of CNS and peripheral stimulation.

- B. **Pharmacokinetics.** All these drugs are well absorbed orally and have large volumes of distribution ($V_d = 3-33$ L/kg, except pemoline, with $V_d = 0.2-0.6$ L/kg), and they are generally extensively metabolized by the liver. Excretion of most amphetamines is highly dependent on urine pH, with amphetamines being more rapidly eliminated in an acidic urine (see also Table II-59, p 381).

- II. **Toxic dose.** These drugs generally have a low therapeutic index, with toxicity at levels only slightly above usual doses. However, a high degree of tolerance can develop after repeated use. Acute ingestion of more than 1 mg/kg of dextroamphetamine (or an equivalent dose of other drugs; see Table II-1) should be considered potentially life threatening.

III. Clinical presentation

- A. **Acute CNS effects** of intoxication include euphoria, talkativeness, anxiety, restlessness, agitation, seizures, and coma. Intracranial hemorrhage may occur owing to hypertension or cerebral vasculitis.

TABLE II-1. COMMON AMPHETAMINELIKE DRUGS^a

Drugs	Clinical Indications	Typical Adult Dose (mg)	Half-Life (hours) ^b
Benzphetamine	Anorectant	25–50	6–12
Dexfenfluramine ^c	Anorectant	15	17–20
Dextroamphetamine	Narcolepsy, hyperactivity (children)	5–15	10–12
Diethylpropion	Anorectant	25, 75 (SR ^d)	2.5–6
Fenfluramine ^c	Anorectant	20–40	10–30
Mazindol	Anorectant	1–2	10
Methamphetamine	Narcolepsy, hyperactivity (children)	5–15	4–5
Methylphenidate	Hyperactivity (children)	5–20	2–7
Pemoline	Narcolepsy, hyperactivity (children)	18.7–75	9–14
Phendimetrazine	Anorectant	35, 105 (SR ^d)	5–12.5
Phenmetrazine	Anorectant	25,75 (SR ^d)	
Phentermine	Anorectant	8, 30 (SR ^d)	7–24

^aSee also Table II-32, p 248 (LSD and other hallucinogens).

^bHalf-life variable, dependent on urine pH

^cWithdrawn from the US market September 1997.

^dSR = Sustained-release formulation.

- B. Acute peripheral manifestations** include sweating, tremor, muscle fasciculations and rigidity, tachycardia, hypertension, acute myocardial ischemia, and infarction (even with normal coronary arteries). Inadvertent intra-arterial injection may cause vasospasm resulting in gangrene; this has also occurred with oral use of DOB (2,5-dimethoxy-4-bromoamphetamine; see Lysergic Acid Diethylamide [LSD] and Other Hallucinogens, p 247).
- C. Death** may be caused by ventricular arrhythmia, status epilepticus, intracranial hemorrhage, or hyperthermia. **Hyperthermia** frequently results from seizures and muscular hyperactivity and may cause brain damage, rhabdomyolysis, and myoglobinuric renal failure (see p 21).
- D. Chronic effects** of amphetamine abuse include weight loss, cardiomyopathy, pulmonary hypertension, dental changes, stereotypic behavior (such as picking at the skin), paranoia, and paranoid psychosis. Psychiatric disturbances may persist for days or weeks. After cessation of habitual use, patients may suffer fatigue, hypersomnia, hyperphagia, and depression lasting several days.
- E.** Prolonged use (usually 3 months or longer) of fenfluramine or dexfenfluramine in combination with phentermine (“fen-phen”) has been associated with an increased risk of pulmonary hypertension and of fibrotic valvular heart disease (primarily aortic, mitral, and tricuspid regurgitation). The pathology of the valvular disease is identical to that seen with carcinoid syndrome.
- F.** Illicit manufacture of methamphetamine can expose the “chemist” and his or her family to various toxic chemicals including corrosive agents, solvents, and heavy metals.
- IV. Diagnosis** is usually based on a history of amphetamine use and clinical features of sympathomimetic drug intoxication.
- A. Specific levels.** Amphetamines and many related drugs can be detected in urine and gastric samples, providing confirmation of exposure. However, quantitative serum levels do not correlate well with severity of clinical effects and are not generally available. Amphetamine derivatives and adrenergic amines may cross-react in immunoassays (see Table I-33, p 43), and distin-

guishing the specific drug requires confirmatory testing (eg, with thin-layer chromatography, gas chromatography, or mass spectrometry). Selegiline (a drug used in Parkinson's disease) is metabolized to *l*-amphetamine and *l*-methamphetamine, and Clobenzorex (an anorectic drug sold in Mexico) is metabolized to amphetamine; these drugs can produce a positive result on urine and blood tests for amphetamines.

- B. Other useful laboratory studies** include electrolytes, glucose, BUN and creatinine, CPK, urinalysis, urine dipstick test for occult hemoglobin (positive in patients with rhabdomyolysis with myoglobinuria), ECG and ECG monitoring, and CT scan of the head (if hemorrhage is suspected). Echocardiogram and right heart catheterization may be useful for detecting valvular disease or pulmonary hypertension.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat agitation (see p 24), seizures (p 22), coma (p 19), and hyperthermia (p 21) if they occur.
3. Continuously monitor the temperature, other vital signs, and the ECG for a minimum of 6 hours.

B. Specific drugs and antidotes. There is no specific antidote.

1. **Hypertension** (see p 17) is best treated with a parenteral vasodilator such as phentolamine (p 487) or nitroprusside (p 477).
2. Treat **tachyarrhythmias** (pp 12–13) with propranolol (see p 496) or esmolol (p 443).
3. Treat **arterial vasospasm** as described for ergots (p 189).

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. Dialysis and hemoperfusion are not effective. Repeat-dose charcoal has not been studied. Renal elimination of dextroamphetamine may be enhanced by acidification of the urine, but this is not recommended because of the risk of aggravating the nephrotoxicity of myoglobinuria.

► ANESTHETICS, LOCAL

Neal L. Benowitz, MD

Local anesthetics are widely used to provide anesthesia via local subcutaneous injection; topical application to skin and mucous membranes; and epidural, spinal, and regional nerve blocks. In addition, lidocaine (see p 462) is used intravenously as an antiarrhythmic agent and cocaine (see p 171) is a popular drug of abuse. Commonly used agents are divided into two chemical groups: ester-linked and amide-linked (Table II–2).

Toxicity from local anesthetics (other than cocaine) is usually caused by therapeutic overdosage (ie, excessive doses for local nerve blocks), inadvertent acceleration of intravenous infusions (lidocaine), or accidental injection of products meant for dilution (eg, 20% lidocaine) instead of those formulated for direct administration (2% solution). Acute injection of lidocaine has also been used as a method of homicide.

TABLE II-2. COMMON LOCAL ANESTHETICS

Anesthetic	Usual Half-Life	Maximum Adult Single Dose ^a (mg)
Ester-linked		
Benzocaine ^b		N/A
Benzonatate ^c		200
Butacaine ^b		N/A
Butamben ^b		N/A
Chlorprocaine	1.5–6 min	800
Cocaine ^b	1–2.5 h	N/A
Cyclomethylcaine ^b		N/A
Hexylcaine ^b		N/A
Procaine	7–8 min	600
Proparacaine ^b		N/A
Propoxycaine		75
Tetracaine	5–10 min	15
Amide-linked		
Articaine	1–2 h	500
Bupivacaine	2–5 h	400
Dibucaine		10
Etidocaine	1.5 h	400
Levobupivacaine	1–3 h	300
Lidocaine	1.2 h	300
Lidocaine with epinephrine	2 h	500
Mepivacaine		400
Prilocaine		600
Other (neither ester- nor amide-linked)		
Dyclonine ^b		N/A
Pramoxine ^b		N/A

^aMaximum single dose for subcutaneous infiltration. N/A, Not applicable.

^bUsed only for topical anesthesia.

^cGiven orally as an antitussive.

I. Mechanism of toxicity

- A. Local anesthetics bind to sodium channels in nerve fibers, blocking the sodium current responsible for nerve conduction and thereby increasing the threshold for conduction and reversibly slowing or blocking impulse generation. In therapeutic concentrations, this results in local anesthesia. In high concentrations, such actions may result in CNS and cardiovascular toxicity.
- B. In addition, some local anesthetics (eg, benzocaine, prilocaine) have been reported to cause methemoglobinemia (see p 261).
- C. **Pharmacokinetics.** With local subcutaneous injection, peak blood levels are reached in 10–60 minutes, depending on the vascularity of the tissue and whether a vasoconstrictor such as epinephrine has been added. **Ester-type** drugs are rapidly hydrolyzed by plasma cholinesterase and have short half-lives. **Amide-type** drugs are metabolized by the liver, have a longer duration

of effect, and may accumulate after repeated doses in patients with hepatic insufficiency. For other kinetic values, see Table II–59, p 381.

II. Toxic dose. Systemic toxicity occurs when brain levels exceed a certain threshold. Toxic levels can be achieved with a single large subcutaneous injection, with rapid intravenous injection of a smaller dose, or by accumulation of drug with repeated doses. The recommended maximum single subcutaneous doses of the common agents are listed in Table II–2.

III. Clinical presentation

A. Toxicity owing to local anesthetic effects includes prolonged anesthesia and, rarely, permanent sensory or motor deficits. Spinal anesthesia may block nerves to the muscles of respiration, causing respiratory arrest, or may cause sympathetic blockade, resulting in hypotension.

B. Toxicity resulting from systemic absorption of local anesthetics affects primarily the CNS, with headache, confusion, perioral paresthesias, slurred speech, muscle twitching, convulsions, coma, and respiratory arrest. Cardiotoxic effects include sinus arrest, atrioventricular block, asystole, and hypotension.

C. Methemoglobinemia (see also p 261) may occur after exposure to benzocaine or prilocaine.

D. Allergic reactions (bronchospasm, hives, and shock) are uncommon and occur almost exclusively with ester-linked local anesthetics. Methylparaben, used as a preservative in some multidose vials, may be the cause of some reported hypersensitivity reactions.

E. Features of toxicity caused by **cocaine** are discussed on p 171.

IV. Diagnosis is based on a history of local anesthetic use and typical clinical features. Abrupt onset of confusion, slurred speech, or convulsions in a patient receiving lidocaine infusion for arrhythmias should suggest lidocaine toxicity.

A. Specific levels. Serum levels of some local anesthetics may confirm their role in producing suspected toxic effects, but these must be obtained promptly because the levels rapidly fall.

1. Serum concentrations of lidocaine greater than 6–10 mg/L are considered toxic.

2. Lidocaine is often detected in comprehensive urine toxicology screening as a result of use either as a local anesthetic (eg, for minor procedures in the emergency department) or as a cutting agent for drugs of abuse.

B. Other useful laboratory studies include electrolytes, glucose, BUN and creatinine, ECG monitoring, arterial blood gases or pulse oximetry, and methemoglobin level (benzocaine).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).

2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), arrhythmias (p 13), and anaphylaxis (p 27) if they occur. Extracorporeal circulatory assistance (eg, balloon pump or partial cardiopulmonary bypass) has been used for short-term support for patients with acute massive overdose with 20% lidocaine solution.

3. Monitor vital signs and ECG for at least 6 hours.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination

1. **Parenteral exposure.** Decontamination is not feasible.

2. **Ingestion** (see p 47)

a. Prehospital. Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures.

b. Hospital. Administer activated charcoal. Consider gastric lavage only for large recent ingestion.

D. Enhanced elimination. Because lidocaine has a moderate volume of distribution, hemoperfusion is potentially beneficial, particularly after a massive

overdose or when metabolic elimination is impaired because of circulatory collapse or severe liver disease.

Fisher MA et al: Toxic methemoglobinemia: a rare but serious complication of transesophageal echocardiography. *Can J Cardiol* 1998 Sep;14(9):1157–1160. [PMID: 9779022] (Caused by topical benzocaine applied to the esophagus for the procedure.)

► ANGIOTENSIN BLOCKERS AND ACE INHIBITORS

Shireen Banerji, PharmD

The angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor (AR) blockers are widely used for the treatment of hypertension, heart failure, and patients after myocardial infarction. There are currently at least 10 ACE inhibitors and 7 AR blockers marketed in the United States.

I. Mechanism of toxicity

- A. ACE inhibitors reduce vasoconstriction and aldosterone activity by blocking the enzyme that converts angiotensin I to angiotensin II. Angiotensin receptor blockers directly inhibit the action of angiotensin II.
- B. All of the ACE inhibitors except captopril and lisinopril must be metabolized to their active moieties (eg, enalapril is converted to enalaprilat).
- C. Angioedema and cough associated with ACE inhibitors is thought to be mediated by bradykinin, which is normally broken down by the angiotensin-converting enzyme. However, it has also been reported with AR blockers, which do not alter bradykinin elimination.
- D. **Pharmacokinetics.** (See also Table II–59.) The volume of distribution (Vd) of ACE inhibitors is fairly small (eg, 0.7 L/kg for captopril). The parent drugs are rapidly converted to their active metabolites, with half-lives of 0.75–1.5 hours. The active metabolites have elimination half-lives of 5.9–35 hours. The AR blockers have half-lives of 5–24 hours; losartan has an active metabolite.

- II. **Toxic dose.** Only mild toxicity has resulted from most reported overdoses of up to 7.5 g of captopril, 440 mg of enalapril (serum level 2.8 mg/L at 15 hours), and 420 mg of lisinopril. A 75-year-old man was found dead after ingesting approximately 1125 mg of captopril, and he had a postmortem serum level of 60.4 mg/L. A 33-year-old survived a captopril level of 5.98 mg/L. A 45-year-old woman recovered without sequelae after intentional ingestion of 160 mg of candesartan cilexetil along with several other drugs.

III. Clinical presentation

- A. **Hypotension**, usually responsive to fluid therapy, has been reported with acute overdose. Bradycardia may also occur.
- B. **Hyperkalemia** has been reported with therapeutic use, especially in patients with renal insufficiency and those taking nonsteroidal anti-inflammatory drugs.
- C. **Bradykinin-mediated effects** in patients taking therapeutic doses of ACE inhibitors include dry cough (generally mild but often persistent and annoying); and **acute angioedema**, usually involving the tongue, lips, and face, which may lead to life-threatening airway obstruction.

IV. Diagnosis is based on a history of exposure.

- A. **Specific levels.** Blood levels are not readily available and do not correlate with clinical effects.
- B. **Other useful laboratory studies** include electrolytes, glucose, blood urea nitrogen (BUN), and creatinine.

V. Treatment

A. Emergency and supportive measures

1. If hypotension occurs, treat it with supine positioning and intravenous fluids (see p 16). Vasopressors are rarely necessary.

2. Treat angioedema with usual measures (eg, diphenhydramine, corticosteroids) and discontinue the ACE inhibitor. Switching to an AR blocker may not be appropriate as angioedema has also been reported with these agents.
- B. Specific drugs and antidotes.** No specific antidote is available.
- C. Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal, if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. Enhanced elimination.** Hemodialysis may effectively remove these drugs but is not likely to be indicated clinically.

Abdi R et al: Angiotensin II receptor blocker-associated angioedema: on the heels of ACE inhibitor angioedema. *Pharmacotherapy* 2002;22(9):1173–1175. [PMID: 12222553] (Case report in a patient taking losartan who had previously developed angioedema on an ACE inhibitor.)

Howes LG, Tran D: Can angiotensin receptor antagonists be used safely in patients with previous ACE inhibitor-induced angioedema? *Drug Saf* 2002;25(2):73–76. [PMID: 11888349] (Angioedema may also occasionally occur with angiotensin receptor blockers, and is more likely in patients who experienced angioedema while receiving ACE inhibitors.)

► ANTIARRHYTHMIC DRUGS

Neal L. Benowitz, MD

Because of their actions on the heart, antiarrhythmic drugs are extremely toxic and overdoses are often life threatening. Several classes of antiarrhythmic drugs are discussed elsewhere in Section II: type Ia drugs (quinidine, disopyramide, and procainamide; p 324); type II drugs (beta blockers, p 131); type IV drugs (calcium antagonists, p 144); and the older type Ib drugs (lidocaine, p 74; and phenytoin, p 303). This section describes toxicity caused by type Ib (tocainide and mexiletine); type Ic (flecainide, encainide, propafenone, and moricizine); and type III (bretylium and amiodarone) antiarrhythmic drugs. Sotalol, which also has type III antiarrhythmic actions, is discussed in the section on beta-adrenergic blockers (see p 131).

I. Mechanism of toxicity

- A. Type I drugs** in general act by inhibiting the fast sodium channel responsible for initial cardiac cell depolarization and impulse conduction. Type Ia and type Ic drugs (which also block potassium channels) slow depolarization and conduction in normal cardiac tissue, and even at normal therapeutic doses the QT (types Ia and Ic) and QRS intervals (type Ic) are prolonged. Type Ib drugs slow depolarization primarily in ischemic tissue and have little effect on normal tissue or on the ECG. In overdose, all type I drugs have the potential to markedly depress myocardial automaticity, conduction, and contractility.
- B. Type II and type IV drugs** act by blocking beta-adrenergic receptors (type II) or calcium channels (type IV). Their actions are discussed elsewhere (type II, p 131; type IV, p 144).
- C. Type III drugs** act primarily by blocking potassium channels to prolong the duration of the action potential and the effective refractory period, resulting in QT interval prolongation at therapeutic doses.
 1. Intravenous administration of **bretylium** initially causes release of catecholamines from nerve endings, followed by inhibition of catecholamine release.

- 2. Amiodarone** is also a noncompetitive beta-adrenergic blocker and has calcium channel blocking effects, which may explain its tendency to cause bradyarrhythmias. Amiodarone may also release iodine, and chronic use has resulted in altered thyroid function (both hyper- and hypothyroidism).
- D. Relevant pharmacokinetics.** All drugs discussed in this section are widely distributed to body tissues. Most are extensively metabolized, but significant fractions of tocainide (40%), flecainide (30%), and bretylium (> 90%) are excreted unchanged by the kidneys. (See also Table II–59, p 381).
- II. Toxic dose.** In general, these drugs have a narrow therapeutic index, and severe toxicity may occur slightly above or sometimes even within the therapeutic range, especially if combinations of antiarrhythmic drugs are taken together.
- A.** Ingestion of **twice the daily therapeutic dose** should be considered potentially life threatening (usual therapeutic doses are given in Table II–3).
- B.** An exception to this rule of thumb is amiodarone, which is so extensively distributed to tissues that even massive single overdoses produce little or no toxicity (toxicity usually occurs only after accumulation during chronic amiodarone dosing).
- III. Clinical presentation**
- A. Tocainide and mexiletine**
- 1. Side effects** with therapeutic use may include dizziness, paresthesias, tremor, ataxia, and gastrointestinal disturbance.
 - 2. Overdose** may cause sedation, confusion, coma, seizures, respiratory arrest, and cardiac toxicity (sinus arrest, atrioventricular [AV] block, asystole,

TABLE II–3. ANTIARRHYTHMIC DRUGS

Class	Drug	Usual Half-Life (hours)	Therapeutic Daily Dose (mg)	Therapeutic Serum Levels (mg/L)	Major Toxicity ^a
Ia	Quinidine and related (p 324)				
Ib	Tocainide	11–15	1200–2400	4–10	S,B,H
	Mexiletine	10–12	300–1200	0.8–2	S,B,H
	Lidocaine (p 74)				
	Phenytoin (p 303)				
Ic	Flecainide	14–15	200–600	0.2–1	B,V,H
	Encainide ^{b, d}	2–11	75–300	^b	S,B,V,H
	Propafenone ^b	2–10 ^c	450–900	0.5–1	S,B,V,H
	Moricizine	1.5–3.5	600–900	0.02–0.18	B,V,H
II	Beta blockers (p 131)				
III	Amiodarone	50 days	200–600	1.0–2.5	B,V,H
	Bretylium	5–14	5–10 mg/kg (IV loading dose)	1–3	H
	Sotalol (p 131)				
IV	Calcium antagonists (p 144)				

^aMajor toxicity: S = Seizures H = Hypotension
B = Bradyarrhythmias V = Ventricular arrhythmias

^bActive metabolite may contribute to toxicity; level not established.

^cGenetically slow metabolizers may have half-lives of 10–32 hours. Also, metabolism is nonlinear, so half-lives may be longer in patients with overdose.

^dEncainide no longer sold in the United States.

and hypotension). As with lidocaine, the QRS and QT intervals are usually normal, although they may be prolonged after massive overdose.

B. Flecainide, encainide, propafenone, and moricizine

1. **Side effects** with therapeutic use include dizziness, blurred vision, headache, and gastrointestinal upset. Ventricular arrhythmias (monomorphic or polymorphic ventricular tachycardia; see p 13) may occur at therapeutic levels, especially in persons receiving high doses and those with reduced ventricular function.
2. **Overdose** causes hypotension, bradycardia, AV block, and asystole. The QRS and QT intervals are prolonged, and ventricular arrhythmias may occur.

C. Bretylium

1. The major toxic **side effect** of bretylium is hypotension caused by inhibition of catecholamine release. Orthostatic hypotension may persist for several hours.
2. After **rapid intravenous injection**, transient hypertension, nausea, and vomiting may occur.

D. Amiodarone

1. **Acute overdose** in a person not already on amiodarone is not expected to cause toxicity.
2. With **chronic use**, amiodarone may cause ventricular arrhythmias (monomorphic or polymorphic ventricular tachycardia; see p 14) or bradyarrhythmias (sinus arrest, AV block). Amiodarone may cause pneumonitis or pulmonary fibrosis, hepatitis, photosensitivity dermatitis, corneal deposits, hypothyroidism or hyperthyroidism, tremor, ataxia, and peripheral neuropathy.

IV. Diagnosis is usually based on a history of antiarrhythmic drug use and typical cardiac and electrocardiographic findings. Syncope in any patient taking these drugs should suggest possible drug-induced arrhythmia.

A. Specific levels. Serum levels are available for most type Ia and type Ib drugs (Table II-3); however, because toxicity is immediately life threatening, measurement of drug levels is used primarily for therapeutic drug monitoring or to confirm the diagnosis rather than to determine emergency treatment. The following antiarrhythmic drugs may be detected in *comprehensive* urine toxicology screening: diltiazem, lidocaine, metoprolol, phenytoin, propranolol, quinidine, and verapamil.

B. Other useful laboratory studies include electrolytes, glucose, BUN and creatinine, liver enzymes, thyroid panel (chronic amiodarone), and ECG and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1-7).
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and arrhythmias (pp 10-15) if they occur. **Note:** Type Ia antiarrhythmic agents should not be used to treat cardiotoxicity caused by type Ia, type Ic, or type III drugs.
3. Continuously monitor vital signs and ECG for a minimum of 6 hours after exposure, and admit the patient for 24 hours of intensive monitoring if there is evidence of toxicity.

B. Specific drugs and antidotes. In patients with intoxication by type Ia or type Ic drugs, QRS prolongation, bradyarrhythmias, and hypotension may respond to **sodium bicarbonate**, 1-2 mEq/kg IV (see p 419). The sodium bicarbonate reverses cardiac-depressant effects caused by inhibition of the fast sodium channel.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for large recent ingestions.

D. Enhanced elimination. Owing to extensive tissue binding with resulting large volumes of distribution, dialysis and hemoperfusion are not likely to be effective.

tive for most of these agents. Hemodialysis may be of benefit for tocainide or flecainide overdose in patients with renal failure, but prolonged and repeated dialysis would be necessary. No data are available on the effectiveness of repeat-dose charcoal.

► ANTIBACTERIAL AGENTS

Olga F. Woo, PharmD

The antibiotic class of drugs has proliferated immensely since the first clinical use of sulfonamide in 1936 and the mass production of penicillin in 1941. In general, harmful effects have resulted from allergic reactions or inadvertent intravenous overdose. Serious toxicity from a single acute ingestion is rare. Table II–4 lists common and newer antibacterial agents and their toxicities.

- I. **Mechanism of toxicity.** The precise mechanisms underlying toxic effects vary depending on the agent and are not well understood. In some cases, toxicity is caused by an extension of pharmacologic effects, while in other cases allergic or idiosyncratic reactions are responsible. Also, be aware that some intravenous preparations may contain preservatives such as benzyl alcohol, or large amounts of potassium or sodium. Finally, drug interactions may increase toxic effects by inhibiting metabolism of the antibiotic.
- II. **Toxic dose.** The toxic dose is highly variable, depending on the agent. Life-threatening allergic reactions may occur after subtherapeutic doses in hypersensitive individuals.
- III. **Clinical presentation.** After acute oral overdose, most agents cause only nausea, vomiting, and diarrhea. Specific features of toxicity are described in Table II–4.
- IV. **Diagnosis** is usually based on the history of exposure.
 - A. **Specific levels.** Serum levels for most commonly used antibiotics are usually available. Levels are particularly useful for predicting toxic effects of **aminoglycosides, chloramphenicol, and vancomycin**.
 - B. **Other useful laboratory studies** include complete blood count (CBC), electrolytes, glucose, BUN and creatinine, liver function tests, urinalysis, and methemoglobin level (for patients with dapsone overdose).
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), anaphylaxis (p 27), and hemolysis (see Rhabdomyolysis, p 27) if they occur.
 3. Replace fluid losses resulting from gastroenteritis with intravenous crystalloids.
 4. Maintain steady urine flow with fluids to alleviate crystalluria from overdoses of sulfonamides, ampicillin, and amoxicillin.
 - B. **Specific drugs and antidotes**
 1. **Trimethoprim** poisoning: administer **leucovorin** (folinic acid; see p 460). Folic acid is not effective.
 2. **Dapsone** overdose (see also p 179): administer **methylene blue** (p 466) for symptomatic methemoglobinemia.
 - C. **Decontamination** (see p 46)
 1. **Prehospital.** Administer activated charcoal, if available.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
 - D. **Enhanced elimination.** Most antibiotics are excreted unchanged in the urine, so maintenance of adequate urine flow is important. The role of forced diure-

TABLE II-4. COMMON ANTIBACTERIAL AGENTS AND THEIR TOXICITIES

Drug	Half-Life*	Toxic Dose or Serum Level	Toxicity
Aminoglycosides			
Amikacin	2–3 h	> 35 mg/L	Ototoxicity to vestibular and cochlear cells; nephrotoxicity causing proximal tubular damage and acute tubular necrosis; competitive neuromuscular blockade if given rapidly intravenously with other neuromuscular blocking drugs. Threshold for toxic effects will vary with the drug and the dosage schedule.
Gentamicin	2 h	> 12 mg/L	
Kanamycin	2–3 h	> 30 mg/L	
Neomycin		0.5–1 g/d	
Streptomycin	2.5 h	> 40–50 mg/L	
Tobramycin	2–2.5 h	> 10 mg/L	
Bacitracin		Unknown	Ototoxicity and nephrotoxicity.
Cephalosporins			
Cefazolin	90–120 min	Unknown	Convulsions reported in patients with renal insufficiency; coagulopathy associated with cefazolin.
Cephalothin			
Cephalexin		6 g/d	Proximal tubular necrosis.
Cefaclor	0.6–0.9 h		Neutropenia
Cefoperazone	102–156 min	3–4 mg/L	One case of symptomatic hepatitis. All of these antibiotics have the <i>N</i> -methyltetrahydrothiol side chain which may inhibit aldehyde dehydrogenase to cause a disulfiramlike interaction with ethanol (see p 186) and coagulopathy (inhibition of vitamin K production).
Cefamandole	30–60 min		
Cefotetan	3–4.6 h		
Moxalactam	114–150 min		
Cefmetazole	72 min		
Ceftriaxone	4.3–4.6 h (extensive excretion in bile)	Intravenous bolus over < 3–5 min	Pseudolithiasis (“gall-bladder sludge”). Should be administered IV over 30 min.
Chloramphenicol	4 h	> 40 mg/L	Leukopenia, reticulocytopenia; circulatory collapse (gray baby syndrome).
Dapsone	10–50 h	As little as 100 mg in an 18-month-old	Methemoglobinemia, sulfhemoglobinemia, hemolysis; metabolic acidosis; hallucinations, confusion; hepatitis (see p 179).
Ethambutol		> 15 mg/kg/day	Optic neuritis, red/green color blindness, peripheral neuropathy.
Erythromycin	1.4 h	Unknown	Abdominal pain; idiosyncratic hepatotoxicity with estolate salt. Interaction with fluoroquinolones, cisapride, disopyramide, terfenadine, or astemizole can induce QT prolongation and torsade de pointes; can elevate serum theophylline levels. (Inhibits hepatic cytochrome P-450 3A4.) Administration of more than 4 g/day may cause tinnitus, ototoxicity.
Gramicidin		Unknown	Hemolysis.
Isoniazid (INH)	0.5–4 h	1–2 g orally	Convulsions, metabolic acidosis (see p 233); hepatotoxicity with chronic use.
Lincomycin, clindamycin	4.4–6.4 h 2.4–3 h	Unknown	Hypotension and cardiopulmonary arrest after rapid intravenous administration.
Linezolid	4.5–5.5 h	Duration-related (more than 2 weeks)	Thrombocytopenia.
Metronidazole	8.5 h	5 g/d	Convulsions; at therapeutic doses may cause disulfiramlike interaction with ethanol (see p 186).
Nalidixic acid	1.1–2.5 h	50 mg/kg/d	Seizures, hallucinations, confusion; visual disturbances; metabolic acidosis; intracranial hypertension.

(continued)

TABLE II-4. COMMON ANTIBACTERIAL AGENTS AND THEIR TOXICITIES (CONTINUED)

Drug	Half-Life*	Toxic Dose or Serum Level	Toxicity
Nitrofurantoin	20 min	Unknown	Hemolysis in G6PD-deficient patients.
Penicillins			
Penicillin	30 min	10 million units/d IV, or CSF > 5 mg/L	Seizures with single high dose or chronic excessive doses in patients with renal dysfunction.
Methicillin	30 min	Unknown	Interstitial nephritis, leukopenia.
Nafcillin	1.0 h	Unknown	Neutropenia.
Ampicillin, amoxicillin	1.5 h 1.3 h	Unknown	Acute renal failure caused by crystal deposition.
Penicillins, anti-pseudomonal			
Carbenicillin	1.0–1.5	> 300 mg/kg/d or > 250 mg/L	Bleeding disorders due to impaired platelet function; hypokalemia. Risk of toxicity higher in patients with renal insufficiency.
Mezlocillin	0.8–1.1	> 300 mg/kg/d	
Piperacillin	0.6–1.2	> 300 mg/kg/d	
Ticarcillin	1.0–1.2	> 275 mg/kg/d	
Polymyxins	4.3–6 h	30,000 units/kg/d	Nephrotoxicity and noncompetitive neuromuscular blockade.
Polymyxin B			
Polymyxin E		250 mg IM in a 10-month-old	
Pyrazinamide	9–10 h	40–50 mg/kg/day for prolonged period	Hepatotoxicity, hyperuricemia.
Quinolones			May damage growing cartilage; may cause blood glucose alterations; hemolysis in patients with G6PD deficiency; exacerbation of myasthenia gravis; acute renal failure.
Ciprofloxacin	4 h		Crystalluria associated with doses above daily maximum and with alkaline urine. Inhibits cytochrome P-450 1A2.
Norfloxacin	3–4 h		Crystalluria associated with doses above daily maximum and with alkaline urine.
Trovafoxacin	9.1–12.2 h		Pancreatitis.
Alatrofloxacin	9.4–12.7 h		Pancreatitis.
Rifampin	1.5–5 h	100 mg/kg/d	Facial edema, pruritus; headache, vomiting, diarrhea; red urine and tears.
Spectinomycin	1.2–2.8 h		Acute toxicity not reported.
Tetracyclines	6–12 h	> 1 g/d in infants	Benign intracranial hypertension. Degradation products (eg, expired prescription) are nephrotoxic, may cause Fanconi-like syndrome. Some products contain sulfites.
		> 4 g/d in pregnancy or > 15 mg/L	Acute fatty liver.
Demeclocycline	10–17 h	Chronic	Nephrogenic diabetes insipidus.
Minocycline	11–26 h	Chronic	Vestibular symptoms.
Sulfonamides		Unknown	Acute renal failure caused by crystal deposition.

(continued)

TABLE II-4. COMMON ANTIBACTERIAL AGENTS AND THEIR TOXICITIES (CONTINUED)

Drug	Half-Life*	Toxic Dose or Serum Level	Toxicity
Trimethoprim	8–11 h	Unknown	Bone marrow depression; methemoglobinemia; hyperkalemia
Vancomycin	4–6 h	> 80 mg/L	Ototoxic and nephrotoxic. Hypertension, skin rash/flushing ("red-man syndrome") associated with IV administration.

*Normal renal function.

sis is unclear. Hemodialysis is not usually indicated, except perhaps in patients with renal dysfunction and a high level of a toxic agent.

1. Charcoal hemoperfusion effectively removes **chloramphenicol** and is indicated after a severe overdose with a high serum level and metabolic acidosis.
2. **Dapsone** undergoes enterohepatic recirculation and is more rapidly eliminated with repeat-dose activated charcoal (see p 57).

Hoffmann IM et al: Acute renal failure in cystic fibrosis: association with inhaled tobramycin therapy. *Pediatr Pulmonol* 2002;34(5):375–377. [PMID: 12357482] (A 20-year-old patient developed acute nonoliguric renal failure associated with inhaled tobramycin therapy.)

► ANTICHOLINERGICS

Beth H. Manning, PharmD

Anticholinergic intoxication can occur with a wide variety of prescription and over-the-counter medications and numerous plants and mushrooms. Common drugs that possess anticholinergic activity include antihistamines (see p 96), antipsychotics (see p 107), antispasmodics, skeletal muscle relaxants (see p 339), and tricyclic antidepressants (see p 90). *Common combination products containing anticholinergic drugs* include Atrohist™, Donnagel™, Donnatal™, Hyland's Teething Tablets™, Lomotil™, Motofen™, Ru-Tuss™, Urised™, and Urispas™. Common anticholinergic medications are described in Table II-5. Plants and mushrooms containing anticholinergic alkaloids include jimsonweed (*Datura stramonium*), deadly nightshade (*Atropa belladonna*), and the fly agaric (*Amanita muscaria*).

I. Mechanism of toxicity

- A. Anticholinergic agents competitively antagonize the effects of acetylcholine at peripheral muscarinic and central receptors. Exocrine glands, such as those responsible for sweating and salivation, and smooth muscle are mostly affected. The inhibition of muscarinic activity in the heart leads to a rapid heart beat.
 - B. Tertiary amines such as atropine are well absorbed centrally, whereas quaternary amines such as glycopyrrolate have a less central effect.
 - C. **Pharmacokinetics.** Absorption may be delayed because of the pharmacologic effects of these drugs on gastrointestinal motility. The duration of toxic effects can be quite prolonged (eg, benztropine intoxication may persist for 2–3 days). (See also Table II-59, p 381).
- II. **Toxic dose.** The range of toxicity is highly variable and unpredictable. Fatal atropine poisoning has occurred after as little as 1–2 mg was instilled in the eye of a young child. Intramuscular injection of 32 mg of atropine was fatal in an adult.
- III. **Clinical presentation.** The anticholinergic syndrome is characterized by warm, dry, flushed skin; dry mouth; mydriasis; delirium; tachycardia; ileus; and urinary retention. Jerky myoclonic movements and choreoathetosis are common, and

TABLE II-5. COMMON ANTICHOLINERGIC DRUGS^a

Tertiary Amines	Usual Adult Single Dose (mg)	Quarternary Amines	Usual Adult Single Dose (mg)
Atropine	0.4–1	Anisotropine	50
Benztropine	1–6	Clidinium	2.5–5
Biperiden	2–5	Glycopyrrolate	1
Dicyclomine	10–20	Hexocyclium	25
Flavoxate	100–200	Ipratropium bromide	N/A ^b
L-Hyoscyamine	0.15–0.3	Isopropamide	5
Oxybutynin	5	Mepenzolate	25
Oxyphencyclimine	10	Methantheline	50–100
Procyclidine	5	Methscopolamine	2.5
Scopolamine	0.4–1	Propantheline	7.5–15
Tolterodine	2–4	Tridihexethyl	25–50
Trihexyphenidyl	6–10		

^aThese drugs act mainly at muscarinic cholinergic receptors, and are sometimes more correctly referred to as antimuscarinic drugs

^bNot used orally; available as metered-dose inhaler and 0.02% inhalation solution and 0.03% nasal spray.

may lead to rhabdomyolysis. Hyperthermia, coma, and respiratory arrest may occur. Seizures are rare with pure antimuscarinic agents, although they may result from other pharmacologic properties of the drug (eg, tricyclic antidepressants and antihistamines).

IV. Diagnosis is based on a history of exposure and the presence of typical features such as dilated pupils and flushed skin. A trial dose of physostigmine (see below) can be used to confirm the presence of anticholinergic toxicity; rapid reversal of signs and symptoms is consistent with the diagnosis.

A. Specific levels. Concentrations in body fluids are not generally available. Common over-the-counter (OTC) agents are usually detectable on comprehensive urine toxicology screening but are not found on hospital drugs of abuse panels.

B. Other useful laboratory studies include electrolytes, glucose, CPK, arterial blood gases or pulse oximetry, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if needed (see pp 1–7).
2. Treat hyperthermia (see p 21), coma (p 19), rhabdomyolysis (p 27), and seizures (p 22) if they occur.

B. Specific drugs and antidotes

1. A small dose of **physostigmine** (see p 489), 0.5–1 mg IV in an adult, can be given to patients with severe toxicity (eg, hyperthermia, severe delirium, or tachycardia). *Caution:* physostigmine can cause atrioventricular block, asystole, and seizures, especially in patients with tricyclic antidepressant overdose.
2. **Neostigmine**, a peripherally acting cholinesterase inhibitor, may be useful in treating anticholinergic-induced ileus.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. Hemodialysis, hemoperfusion, peritoneal dialysis, and repeat-dose charcoal are not effective in removing anticholinergic agents.

Burns MJ et al: A comparison of physostigmine and benzodiazepines for the treatment of anticholinergic poisoning. *Ann Emerg Med* 2000;35(4):374–381. [PMID: 10736125] (Retrospective study; the authors conclude that physostigmine is safer and more effective than benzodiazepines for treatment of anticholinergic agitation and delirium.)
Isbister GK et al: Treatment of anticholinergic-induced ileus with neostigmine. *Ann Emerg Med* 2001 Dec;38(6):689–693. [PMID: 11719751] (Neostigmine successfully reversed ileus caused by chronic benzotropine abuse.)

► **ANTICONVULSANTS, NEWER**

Freda M. Rowley, PharmD

In the last decade a number of newer anticonvulsants have been introduced, and are being used in a variety of treatment settings, including treatment of partial and generalized seizure disorders, chronic pain syndromes, bipolar disorders, and migraine prophylaxis. Characteristics of several of these drugs are provided in Table II–6.

I. Mechanism of toxicity

A. Felbamate has effects on sodium channels, enhances activity of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), and blocks *N*-methyl-*D*-aspartate (NMDA) receptors.

TABLE II–6. NEWER ANTICONVULSANT DRUGS

Drug	Usual Elimination Half-Life (hours)	Usual Daily Dose (mg/day)	Reported Potential Toxic Effects
Felbamate	20–23 h	1800–4800 mg	Mild CNS depression, nystagmus, ataxia; tachycardia; nausea and vomiting; one case report of acute renal failure (crystalluria). Aplastic anemia, hepatic failure reported with therapeutic use (rare).
Gabapentin	5–7 h	900–3600 mg	Somnolence, dizziness, ataxia, mild tremor, slurred speech, diplopia; tachycardia, hypotension or hypertension; diarrhea.
Lamotrigine	22–36 h	200–500 mg	Lethargy, dizziness, ataxia, stupor, nystagmus, hypertonia, seizures; QRS prolongation; nausea and vomiting; hypokalemia; hypersensitivity: fever, rash (Stevens-Johnson syndrome) hepatitis, renal failure.
Levetiracetam	6–8 h	1000–3000 mg	Drowsiness.
Tiagabine	7–9 h	30–70 mg	Somnolence, confusion, agitation, dizziness, ataxia, depression, weakness, tremor, seizures.
Topiramate	21 h	200–600 mg	Sedation, confusion, slurred speech, ataxia, tremor, anxiety, nervousness.
Vigabatrin	4–8 h	2000–4000 mg	Sedation, confusion, coma, agitation, delirium, psychotic disturbances (hallucinations, delusions, paranoia).
Zonisamide	50–68 h	100–400 mg	Somnolence, ataxia, agitation; bradycardia, hypotension, respiratory depression.

- B. Gabapentin** acts via unknown mechanisms. It has structural similarity to GABA, but does not bind GABA receptors or alter normal levels of GABA in the brain.
- C. Lamotrigine** blocks voltage-sensitive sodium channels, and inhibits the release of excitatory neurotransmitters.
- D. Levetiracetam** acts via unknown mechanisms. It is structurally a GABA derivative, but does not appear to have activity at GABA receptors.
- E. Tiagabine** is thought to enhance GABA activity by binding to GABA recognition sites, and it blocks GABA reuptake at presynaptic neurons.
- F. Topiramate** acts via unknown mechanisms, possibly involving sodium channel blockade and potentiation of GABA effects.
- G. Vigabatrin** prevents inactivation of GABA by irreversible inhibition of GABA transaminase.
- H. Zonisamide** blocks sodium and calcium channels.
- I. Pharmacokinetics.** See Tables II-6 and II-59.
- II. Toxic dose.** There have been few reports of overdose. Toxic effects may be influenced by presence of other medications with CNS activity.
- III. Clinical presentation.** After acute oral overdose, most agents cause some degree of CNS depression. Specific features of potential or reported toxicity of each agent are described in Table II-6.
- IV. Diagnosis** usually based on the history of ingestion or is suspected in any patient on these medications who presents with altered mental status or ataxia.
 - A. Specific levels.** Serum levels are not routinely available and are not likely to be useful for emergency management.
 - B. Other useful laboratory studies** include electrolytes, glucose, creatinine (gabapentin, topiramate), CBC (felbamate), liver transaminases, bilirubin (felbamate), and ECG monitoring (lamotrigine).
- V. Treatment**
 - A. Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1-7). Administer supplemental oxygen.
 2. Treat stupor and coma (see p 19) if they occur. Protect the patient from self-injury caused by ataxia.
 3. Treat agitation and delirium (see p 24) if they occur.
 4. Monitor asymptomatic patients for a minimum of 4-6 hours. Admit symptomatic patients for at least 24 hours after **lamotrigine, felbamate, topiramate, or zonisamide** ingestions.
 - B. Specific drugs and antidotes.** There are no specific antidotes. Sodium bicarbonate (see p 419) has not been studied, but it has been recommended for lamotrigine-induced QRS interval prolongation.
 - C. Decontamination**
 1. **Prehospital.** Administer activated charcoal if available. Ipecac-induced vomiting is not recommended due to the potential for sedation and seizures in this class of agents.
 2. **Hospital.** Administer activated charcoal. Gastric lavage is not necessary after small to moderate ingestions if activated charcoal can be given promptly.
 - D. Enhanced elimination.** Hemodialysis is effective at removing **gabapentin** and **topiramate**, but clinical manifestations are usually responsive to supportive care, making enhanced removal procedures unnecessary.

O'Donnell J, Bateman DN: Lamotrigine overdose in an adult. *J Toxicol Clin Toxicol* 2000;38(6):659-660. [PMID: 11185974] (Ingestion of 4.5 g resulted in ataxia and rotary nystagmus. Peak blood level was 35.8 mg/L with a half-life of 19.5 hours.)

Rengstorff DS et al: Felbamate overdose complicated by massive crystalluria and acute renal failure. *J Toxicol Clin Toxicol* 2000;38(6):667-669. [PMID: 11185976] (20-year-old woman with peak felbamate level of 470 mg/L developed massive crystalluria and hydronephrosis 18 hours after ingestion, resolved with parenteral hydration.)

► **ANTIDEPRESSANTS, GENERAL (NONCYCLIC)**

Neal L. Benowitz, MD

Many noncyclic antidepressants are now available, including trazodone (Desyrel™), nefazodone (Serzone™), fluoxetine (Prozac™), sertraline (Zoloft™), citalopram (Celexa™), escitalopram (Lexapro™), paroxetine (Paxil™), fluvoxamine (Luvox™), venlafaxine (Effexor™), and bupropion (Wellbutrin™). Bupropion is also marketed under the brand name Zyban™ for smoking cessation. Mirtazapine (Remeron™), a tetracyclic antidepressant, has recently become available. In general, these drugs are much less toxic than the **tricyclic antidepressants** (see p 90) and the **monoamine oxidase (MAO) inhibitors** (p 269), although serious effects such as seizures and hypotension occasionally occur. Noncyclic and tricyclic antidepressants are described in Table II-7.

I. Mechanism of toxicity

- A. Most agents cause CNS depression. Bupropion is a stimulant that can also cause seizures, presumably related to inhibition of reuptake of dopamine and norepinephrine.

TABLE II-7. ANTIDEPRESSANTS

	Usual Adult Daily Dose (mg)	Neurotransmitter Effects ^a	Toxicity ^b
Tricyclic antidepressants			
Amitriptyline	75–200	NE, 5-HT	A, H, QRS, Sz
Amoxapine	150–300	NE, DA	A, H, Sz
Clomipramine	100–250	NE, 5-HT	A, H, QRS, Sz
Desipramine	75–200	NE	A, H, Sz
Doxepin	75–300	NE, 5-HT	A, H, QRS, Sz
Imipramine	75–200	NE, 5-HT	A, H, QRS, Sz
Maprotiline	75–300	NE	A, H, QRS, Sz
Nortriptyline	75–150	NE	A, H, QRS, Sz
Protriptyline	20–40	NE	A, H, QRS, Sz
Trimipramine	75–200	NE, 5-HT	A, H, QRS, Sz
Newer, noncyclic drugs			
Bupropion	200–450	DA, ?NE	Sz
Citalopram	20–40	5-HT	Sz, SS
Fluoxetine	20–80	5-HT	Sz, SS
Fluvoxamine	50–300	5-HT	Sz, SS
Mirtazapine	15–45	alpha-2	
Nefazodone	100–600	5-HT, alpha-2	H
Paroxetine	20–50	5-HT	Sz, SS
Sertraline	50–200	5-HT	Sz, SS
Trazodone	50–400	5-HT, alpha-2	H, Sz, SS
Venlafaxine	30–600	5-HT, NE	Sz, SS
Monoamine Oxidase Inhibitors	See p 269		

^aDA = dopamine reuptake inhibitor; NE = norepinephrine reuptake inhibitor; 5-HT = serotonin reuptake inhibitor; alpha-2 = alpha-2-adrenergic receptor blocker.

^bA = anticholinergic effects; H = hypotension; QRS = QRS prolongation; Sz = seizures; SS = serotonin syndrome.

- B. Trazodone and mirtazapine (and nefazodone to a lesser extent) produce peripheral alpha-adrenergic blockade, which can result in hypotension and priapism.
 - C. Serotonin uptake inhibitors (often called selective serotonin reuptake inhibitors or SSRIs) such as fluoxetine, citalopram, sertraline, paroxetine, fluvoxamine, venlafaxine, and trazodone may interact with each other or with chronic use of an MAO inhibitor (see p 269) to produce the “**serotonin syndrome**” (see below and p 21).
 - D. None of the drugs in this group has significant anticholinergic effects.
 - E. **Pharmacokinetics.** These drugs have large volumes of distribution ($V_d = 12\text{--}88\text{ L/kg}$, except trazodone [$V_d = 1.3\text{ L/kg}$]). Most are eliminated via hepatic metabolism (paroxetine is 65% renal). (See also Table II–59, p 381.)
- II. **Toxic dose.** The noncyclic antidepressants generally have a wide therapeutic index, with doses in excess of 10 times the usual therapeutic dose tolerated without serious toxicity. Bupropion can cause seizures in some patients with moderate overdose or even in therapeutic doses.
- III. **Clinical presentation**
- A. **Central nervous system.** The usual presentation after overdose includes ataxia, sedation, and coma. Respiratory depression may occur, especially with co-ingestion of alcohol or other drugs. These agents, particularly bupropion, can cause restlessness, anxiety, and agitation. Tremor and seizures are common with bupropion but occur occasionally after overdose with an SSRI.
 - B. **Cardiovascular** effects are usually minimal, although trazodone can cause hypotension and orthostatic hypotension, bupropion can cause sinus tachycardia, and fluoxetine may cause minor ST-T wave changes.
 - C. **Serotonin syndrome** (see p 21) is characterized by confusion, hypomania, restlessness, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, incoordination, and hyperthermia. This reaction may be seen when a patient taking an MAO inhibitor (p 269) ingests a serotonin uptake blocker. Because of the long duration of effects of MAO inhibitors and most of the serotonin uptake blockers, this reaction can occur up to several days to weeks after either treatment regimen has been discontinued. The syndrome has also been described in patients taking an overdose of an SSRI or combinations of various SSRIs without concomitant MAO inhibitor use.
- IV. **Diagnosis.** A noncyclic antidepressant overdose should be suspected in patients with a history of depression who develop lethargy, coma, or seizures. These agents do not generally affect cardiac conduction, and QRS interval prolongation should suggest a tricyclic antidepressant overdose (see p 90).
- A. **Specific levels.** Blood and urine assays are not routinely available and are not useful for emergency management. These drugs are unlikely to appear on a rapid “drugs of abuse” screen, and may or may not appear on comprehensive toxicology screening, depending on the laboratory.
 - B. **Other useful laboratory studies** include electrolytes, glucose, arterial blood gases or pulse oximetry, and ECG monitoring.
- V. **Treatment**
- A. **Emergency and supportive measures**
 - 1. Maintain an open airway and assist ventilation if needed (see pp 1–7). Administer supplemental oxygen.
 - 2. Treat coma (see p 19), hypotension (p 16), and seizures (p 22) if they occur.
 - B. **Specific drugs and antidotes.** For suspected serotonin syndrome, anecdotal reports claim benefit from cyproheptadine (Periactin), 4 mg orally every hour for 3 doses, or methysergide (Sansert), 2 mg orally every 6 hours for 3 doses, presumably because of the serotonin antagonist effects of these drugs.
 - C. **Decontamination** (see p 47)
 - 1. **Prehospital.** Administer activated charcoal if available. Do not induce emesis.

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. **Enhanced elimination.** Owing to extensive protein binding and large volumes of distribution, dialysis, hemoperfusion, peritoneal dialysis, and repeat-dose charcoal are not effective.

Belson MG, Kelley TR: Bupropion exposures: clinical manifestations and medical outcome. *J Emerg Med* 2002;23(3):223–230. [PMID: 12426011] (Retrospective review of over 7000 calls to poison control centers; seizures occurred in 15% of intentional overdoses.)

Graudins A et al: Treatment of the serotonin syndrome with cyproheptadine. *J Emerg Med* 1998;16(4):615–619. [PMID: 9696181] (Case series of five patients treated successfully with cyproheptadine 4–8 mg orally.)

► ANTIDEPRESSANTS, TRICYCLIC

Neal L. Benowitz, MD

Tricyclic antidepressants are commonly taken in overdose by suicidal patients and represent a major cause of poisoning hospitalizations and deaths. Currently available tricyclic antidepressants are described in Table II–7. Amitriptyline is also marketed in combination with chlorthalidopoxide (Limbitrol™) or perphenazine (Etrafon™ or Triavil™). **Cyclobenzaprine** (Flexeril™), a centrally acting muscle relaxant (see p 339), is structurally related to the tricyclic antidepressants but exhibits minimal cardiotoxic and variable CNS effects. **Newer, noncyclic antidepressants** are discussed on p 88. **Monoamine oxidase inhibitors** are discussed on page 269.

- I. **Mechanism of toxicity.** Tricyclic antidepressant toxicity affects primarily the cardiovascular and central nervous systems.
 - A. **Cardiovascular effects.** Several mechanisms contribute to cardiovascular toxicity:
 1. Anticholinergic effects and inhibition of neuronal reuptake of catecholamines result in tachycardia and mild hypertension.
 2. Peripheral alpha-adrenergic blockade causes vasodilation and contributes to hypotension.
 3. Membrane-depressant (quinidine-like) effects cause myocardial depression and cardiac conduction disturbances by inhibition of the fast sodium channel that initiates the cardiac cell action potential. Metabolic or respiratory acidosis may contribute to cardiotoxicity by further inhibiting the fast sodium channel.
 - B. **Central nervous system effects.** These result in part from anticholinergic toxicity (eg, sedation and coma), but seizures are probably a result of inhibition of reuptake of norepinephrine or serotonin in the brain or other central effects.
 - C. **Pharmacokinetics.** Anticholinergic effects of the drugs may retard gastric emptying, resulting in slow or erratic absorption. Most of these drugs are extensively bound to body tissues and plasma proteins, resulting in very large volumes of distribution and long elimination half-lives (Tables II–7 and II–59). Tricyclic antidepressants are primarily metabolized by the liver, with only a small fraction excreted unchanged in the urine. Active metabolites may contribute to toxicity; several drugs are metabolized to other well-known tricyclic antidepressants (eg, amitriptyline to nortriptyline; imipramine to desipramine).
- II. **Toxic dose.** Most of the tricyclic antidepressants have a narrow therapeutic index so that doses of less than 10 times the therapeutic daily dose may produce severe intoxication. In general, ingestion of 10–20 mg/kg is potentially life threatening.
- III. **Clinical presentation.** Tricyclic antidepressant poisoning may produce any of three major toxic syndromes: anticholinergic effects, cardiovascular effects, and seizures. Depending on the dose and the drug, patients may experience some or

all of these toxic effects. Symptoms usually begin within 30–40 minutes of ingestion but may be delayed owing to slow and erratic gut absorption. Patients who are initially awake may abruptly lose consciousness or develop seizures without warning.

A. Anticholinergic effects include sedation, delirium, coma, dilated pupils, dry skin and mucous membranes, diminished sweating, tachycardia, diminished or absent bowel sounds, and urinary retention. Myoclonic or metonymic jerking is common with anticholinergic intoxication and may be mistaken for seizure activity.

B. Cardiovascular toxicity manifests as abnormal cardiac conduction, arrhythmias, and hypotension.

1. Typical electrocardiographic findings include sinus tachycardia with prolongation of the PR, QRS, and QT intervals. Various degrees of atrioventricular (AV) block may be seen. Prolongation of the QRS complex to 0.12 seconds or longer is a fairly reliable predictor of serious cardiovascular and neurologic toxicity (except in the case of moraine, which causes seizures and coma with no change in the QRS interval).

2. Sinus tachycardia accompanied by QRS interval prolongation may resemble ventricular tachycardia (see Figure I–4, p 12). True ventricular tachycardia and fibrillation may also occur. Atypical or polymorphous ventricular tachycardia (torsade de pointes; see Figure I–7, p 15) associated with QT interval prolongation may occur with therapeutic dosing, but is actually uncommon in overdose. Development of bradyarrhythmias usually indicates a severely poisoned heart and carries a poor prognosis.

3. Hypotension caused by venodilation is common and usually mild. In severe cases, hypotension results from myocardial depression and may be refractory to treatment; some patients die with progressive intractable cardiogenic shock. Pulmonary edema is also common in severe poisonings.

C. Seizures are common with tricyclic antidepressant toxicity and may be recurrent or persistent. The muscular hyperactivity from seizures and myoclonic jerking, combined with diminished sweating, can lead to severe hyperthermia (see p 21), resulting in rhabdomyolysis, brain damage, multisystem failure, and death.

D. Death from tricyclic antidepressant overdose usually occurs within a few hours of admission and may result from ventricular fibrillation, intractable cardiogenic shock, or status epilepticus with hyperthermia. Sudden death several days after apparent recovery has occasionally been reported, but in all such cases there was evidence of continuing cardiac toxicity within 24 hours of death.

IV. Diagnosis. Tricyclic antidepressant poisoning should be suspected in any patient with lethargy, coma, or seizures accompanied by QRS interval prolongation. QRS interval prolongation greater than 0.12 seconds in the limb leads suggests severe poisoning. However, with amoxapine, seizures and coma may occur with no widening of the QRS interval.

A. Specific levels

1. Plasma levels of some of the tricyclic antidepressants can be measured by clinical laboratories. Therapeutic concentrations are usually less than 0.3 mg/L (300 ng/mL). Total concentrations of parent drug plus metabolite of 1 mg/L (1000 ng/mL) or greater are usually associated with serious poisoning. Generally, plasma levels are not used in emergency management because the QRS interval and clinical manifestations of overdose are reliable and more readily available indicators of toxicity.

2. Most tricyclics are detectable on comprehensive urine toxicology screening. Some rapid immunologic techniques are available and have sufficiently broad cross-reactivity to detect several tricyclics. However, use of these assays for rapid screening in the hospital laboratory is not recom-

mended because they may miss some important drugs and give positive results for others present in therapeutic concentrations.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, CPK, urinalysis for myoglobin, arterial blood gases or oximetry, 12-lead ECG and continuous ECG monitoring, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
Caution: Respiratory arrest can occur abruptly and without warning.
2. Treat coma (see p 19), seizures (p 22), hyperthermia (p 21), hypotension (p 16), and arrhythmias (pp 13–15) if they occur. **Note:** Do **not** use procainamide or other type Ia or Ic antiarrhythmic agents for ventricular tachycardia, because these drugs may aggravate cardiotoxicity.
3. Consider cardiac pacing for bradyarrhythmias and high-degree AV block, and overdrive pacing for torsade de pointes.
4. Mechanical support of the circulation (eg, cardiopulmonary bypass) may be useful (based on anecdotal reports) to stabilize patients with refractory shock, allowing time for the body to eliminate some of the drug.
5. If seizures are not immediately controlled with usual anticonvulsants, paralyze the patient with a neuromuscular blocker such as pancuronium (see p 472) to prevent hyperthermia, which may induce further seizures, and lactic acidosis, which aggravates cardiotoxicity. **Note:** Paralysis abolishes the muscular manifestations of seizures, but has no effect on brain seizure activity. After paralysis, ECG monitoring is necessary to determine the efficacy of anticonvulsant therapy.
6. Continuously monitor the temperature, other vital signs, and ECG in asymptomatic patients for a minimum of 6 hours, and admit patients to an intensive care setting for at least 24 hours if there are any signs of toxicity.

B. Specific drugs and antidotes

1. In patients with QRS interval prolongation or hypotension, administer **sodium bicarbonate** (see p 419), 1–2 mEq/kg IV, and repeat as needed to maintain the arterial pH between 7.45 and 7.55. Sodium bicarbonate may reverse membrane-depressant effects by increasing extracellular sodium concentrations and by a direct effect of pH on the fast sodium channel.
2. Hyperventilation, by inducing a respiratory alkalosis (or reversing respiratory acidosis), may also be of benefit but works only transiently and may provoke seizures.
3. Although **physostigmine** was advocated in the past, it should **not** be routinely administered to patients with tricyclic antidepressant poisoning; it may aggravate conduction disturbances, causing asystole, further impair myocardial contractility, worsening hypotension, and contribute to seizures.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures.
2. **Hospital.** Administer activated charcoal. Perform gastric lavage for large ingestions (eg, > 20–30 mg/kg). Gastric emptying is probably not necessary for smaller ingestions if activated charcoal can be given promptly.

D. Enhanced elimination. Owing to extensive tissue and protein binding with a resulting large volume of distribution, dialysis and hemoperfusion are not effective. Although repeat-dose charcoal has been reported to accelerate tricyclic antidepressant elimination, the data are not convincing.

Heard K et al: Treatment of amitriptyline poisoning with ovine antibody to tricyclic antidepressants. *Lancet* 1999;354(9190):1614–1615. [PMID: 10560683] (Experimental anti-TCA antibodies were successful in a 48-year-old man, but are not available yet for clinical use.)

Liebelt EL et al: Serial electrocardiogram changes in acute tricyclic antidepressant overdoses. *Crit Care Med* 1997;25(10):1721–1726. [PMID: 9377889] (Prospective observational study of 36 patients with acute TCA overdose found that both QRS prolongation and rightward axis deviation of the terminal 40 msec were associated with seizures and ventricular arrhythmias, but often persisted even as patients were improving clinically.)

► ANTIDIABETIC AGENTS

Susan Kim, PharmD

Agents used to lower blood glucose are divided into two main groups: oral drugs and insulin products. The oral agents include sulfonylureas, biguanides, glitazones, meglitinides, and alpha-glucosidase inhibitors, each with a different mechanism of action, potency, and duration of activity. All **insulin** products are given by the parenteral route, and all produce effects similar to those of endogenous insulin; they differ by antigenicity and by onset and duration of effect. Table II–8 lists the various available antidiabetic agents. Other drugs and poisons can also cause hypoglycemia (see Table I–25).

I. Mechanism of toxicity

A. Oral agents

1. **Sulfonylureas** lower blood glucose primarily by stimulating endogenous pancreatic insulin secretion and secondarily by enhancing peripheral insulin receptor sensitivity and reducing glycogenolysis.
2. **Meglitinides** also increase pancreatic insulin release, and can cause hypoglycemia in overdose.
3. **Biguanides.** Metformin decreases hepatic glucose production and intestinal absorption of glucose, while increasing peripheral glucose uptake and utilization. It does not stimulate insulin release, and is not likely to produce acute hypoglycemia. Severe **lactic acidosis** is a rare but potentially fatal side effect of metformin (and its predecessor phenformin, no longer available in the United States). It occurs mainly in patients with renal insufficiency, alcoholism, and advanced age, and has occurred after injection of iodinated contrast agents resulted in acute renal failure.
4. **Alpha-glucosidase inhibitors** delay the digestion of ingested carbohydrates, reducing postprandial blood glucose concentrations.
5. **Glitazones** decrease hepatic glucose output and improve target cell response to insulin. Hepatotoxicity has been reported with chronic therapy for all the drugs in this class, and led to removal of troglitazone from the US market.
6. While biguanides, alpha-glucosidase inhibitors, and glitazones are not likely to cause hypoglycemia after acute overdose, they may contribute to the hypoglycemic effects of sulfonylureas, meglitinides, or insulin.

B. Insulin. Blood glucose is lowered directly by the stimulation of cellular uptake and metabolism of glucose. Cellular glucose uptake is accompanied by an intracellular shift of potassium and magnesium. Insulin also promotes glycogen formation and lipogenesis.

C. Pharmacokinetics (see Tables II–8 and II–59)

II. Toxic dose

A. Sulfonylureas. Toxicity depends on the agent and the total amount ingested. Toxicity may also occur owing to drug interactions, resulting in impaired elimination of the oral agent.

1. **Ingestion of a single tablet** of chlorpropamide (250 mg), glipizide (5 mg), or glyburide (2.5 mg) each produced hypoglycemia in children 1–4 years old. Two 500-mg tablets of acetohexamide caused hypoglycemic coma in an adult. In a 79-year-old nondiabetic person, 5 mg of glyburide caused hypoglycemic coma.

TABLE II-8. ANTIDIABETIC AGENTS^a

Agent	Onset (h)	Peak (h)	Duration ^b (h)
Insulins			
Regular insulin	0.5–1	2–3	5–7
Rapid insulin zinc (semilente)	0.5	4–7	12–16
Lispro	0.25	0.5–1.5	6–8
Insulin aspart	0.25	1–3	3–5
Isophane insulin (NPH)	1–2	8–12	18–24
Insulin zinc (lente)	1–2	8–12	18–24
Insulin glargine	1.5	Sustained effect	22–24
Extended zinc insulin (ultralente)	4–8	16–18	36
Protamine zinc insulin (PZI)	4–8	14–20	36
Prolonged insulin zinc	4–8	16–18	36
Sulfonylureas			
Acetohexamide	2	4	12–24
Chlorpropamide	1	3–6	24–72 ^b
Glimepiride		2–3	24
Glipizide [extended-release form]	0.5 [2–3]	1–2 [6–12]	<24 [24]
Glyburide [micronized form]	0.5	4 [2–3]	24 ^b
Tolazamide	1	4–6	14–20
Tolbutamide	1	5–8	6–12
Meglitinides			
Nateglinide	0.25	1–2	1.5–3
Repaglinide	0.5	1–1.5	1–1.5
Biguanides			
Metformin		2	2.5–6
Alpha-glucosidase inhibitors			
Acarbose		N/A ^c	
Miglitol		2–3	2
Glitazones (thiazolidinediones)			
Pioglitazone		2–4	3–7
Rosiglitazone		1–3.5	3–4

^aSee also Table II-55 (p 381).^bDuration of hypoglycemic effects after overdose may be much longer, especially with glyburide and chlorpropamide.^cLess than 2% of an oral dose absorbed systemically.

2. Interactions with the following drugs may increase the risk of hypoglycemia: other hypoglycemics, sulfonamides, propranolol, salicylates, clofibrate, probenecid, pentamidine, valproic acid, dicumarol, cimetidine, MAO inhibitors, and alcohol. In addition, co-ingestion of alcohol may occasionally produce a disulfiram-like interaction (see p 186).

3. Hepatic or renal insufficiency may impair drug elimination and result in hypoglycemia.

B. Repaglinide. A 4-mg dose produced hypoglycemia in a nondiabetic 18-year-old patient.

- C. Metformin.** Lactic acidosis occurred 9 hours after ingestion of 25 g of metformin by an 83-year-old patient, and fatal lactic acidosis and cardiovascular collapse occurred 4 hours after ingestion of 35 g in a 33-year-old patient. Pediatric ingestions up to 1700 mg have been well tolerated.
- D. Insulin.** Severe hypoglycemic coma and permanent neurologic sequelae have occurred after injections of 800–3200 units of insulin. Orally administered insulin is not absorbed and is not toxic.

III. Clinical presentation

- A. Hypoglycemia** may be delayed in onset depending on the agent used and the route of administration (ie, subcutaneous versus intravenous). Manifestations of hypoglycemia include agitation, confusion, coma, seizures, tachycardia, and diaphoresis. The serum potassium and magnesium levels may also be depressed. Note that in patients receiving beta-adrenergic blocking agents (see p 131), many of the manifestations of hypoglycemia (tachycardia, diaphoresis) may be blunted or absent.
 - B. Lactic acidosis** from metformin or phenformin may begin with nonspecific symptoms such as malaise, vomiting, myalgias, and respiratory distress. The mortality rate for severe lactic acidosis is reportedly as high as 50%.
- IV. Diagnosis.** Overdose involving a sulfonylurea, meglitinide, or insulin should be suspected in any patient with hypoglycemia. Other causes of hypoglycemia that should be considered include alcohol ingestion (especially in children) and fulminant hepatic failure.

A. Specific levels

- 1. Serum concentrations of many agents can be determined in commercial toxicology laboratories, but have little utility in acute clinical management.
 - 2. Exogenously administered animal insulin can be distinguished from endogenous insulin (ie, in a patient with hypoglycemia caused by insulinoma) by determination of C peptide (present with endogenous insulin secretion).
- B. Other useful laboratory studies** include glucose, electrolytes, magnesium, and ethanol. If metformin or phenformin is suspected, obtain a venous blood lactate level (gray-top tube).

V. Treatment

A. Emergency and supportive measures

- 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
- 2. Treat coma (see p 19) and seizures (p 22) if they occur.
- 3. Obtain fingerstick blood glucose levels every 1–2 hours until stabilized.

B. Specific drugs and antidotes

- 1. If the patient is hypoglycemic, administer concentrated **glucose** (see p 450). In adults, give 50% dextrose ($D_{50}W$), 1–2 mL/kg; in children, use 25% dextrose ($D_{25}W$), 2–4 mL/kg. Give repeated glucose boluses and administer 5–10% dextrose (D_5-D_{10}) as needed to maintain normal serum glucose concentrations (60–110 mg/dL).
- 2. For patients with a **sulfonylurea** or **meglitinide** overdose, consider intravenous **octreotide** (see p 480) or **diazoxide** (p 433) if 5% dextrose infusions do not maintain satisfactory glucose concentrations.
- 3. Maintaining serum glucose concentrations above 100 mg/dL for the first 12 hours of therapy or longer is often necessary to prevent recurrent hypoglycemia. However, once hypoglycemia resolves (usually 12–24 hours after the ingestion) and the patient no longer requires dextrose infusions, serum glucose concentrations should be allowed to normalize. Follow serum glucose levels closely for several hours after the last dose of dextrose.
- 4. Lactic acidosis due to biguanides may be treated with judicious doses of sodium bicarbonate. Excessive bicarbonate administration may worsen intracellular acidosis.

C. Decontamination (see p 47)

1. Oral agents

- a. **Prehospital.** Administer activated charcoal if available.
- b. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

2. Insulin

- a. Orally ingested insulin is not absorbed and produces no toxicity, so gut decontamination is not necessary.
- b. Local excision of tissue at the site of massive intradermal injection has been performed, but the general utility of this procedure has not been established.

D. Enhanced elimination

1. **Sulfonylureas.** Alkalinization of the urine (see p 55) increases the renal elimination of chlorpropamide. Forced diuresis and dialysis procedures are of no known value for other hypoglycemic agents. The high degree of protein binding of the sulfonylureas suggests that dialysis procedures would not generally be effective. However, charcoal hemoperfusion reduced the serum half-life of chlorpropamide in a patient with renal failure.
2. **Metformin** is removed by hemodialysis, which can also help correct severe lactic acidosis. Continuous venovenous hemodiafiltration has also been recommended.

Hirschberg B et al: Repaglinide-induced factitious hypoglycemia. *J Clin Endocrinol Metab* 2001;86:475–477. [PMID: 11157993] (Recurrent severe hypoglycemia secondary to surreptitious self-administration of repaglinide.)

McLaughlin SA et al: Octreotide: an antidote for sulfonylurea-induced hypoglycemia. *Ann Emerg Med* 2000 Aug;36(2):133–138. [PMID: 10918104] (Case series of nine patients with prompt response to octreotide.)

Teale KF et al: The management of metformin overdose. *Anaesthesia* 1998;53:698–701. [PMID: 9771180] (Three case reports with severe lactic acidosis and cardiovascular collapse, with two deaths.)

► ANTIHISTAMINES

Beth Manning, PharmD

Antihistamines (H_1 receptor antagonists) are commonly found in over-the-counter and prescription medications used for motion sickness, control of allergy-related itching, and cough and cold palliation and as sleep aids (Table II–9). Acute intoxication with antihistamines results in symptoms very similar to those of anticholinergic poisoning. H_2 receptor blockers (cimetidine, ranitidine, and famotidine) inhibit gastric acid secretion but otherwise share no effects with H_1 agents, do not produce significant intoxication, and are not discussed here. *Common combination products containing antihistamines* include ActifedTM, AllerestTM, ContacTM, CoricidinTM, DimetappTM, DristanTM, DrixoralTM, Excedrin PMTM, NyquilTM, NytolTM, PamprinTM, PediacareTM, TavistTM, TriaminicTM, TriaminicTM, Unisom Dual Relief FormulaTM, and Vicks Pediatric Formula 44TM.

I. Mechanism of toxicity

- A. H_1 blocker antihistamines are structurally related to histamine and antagonize the effects of histamine on H_1 receptor sites. They possess anticholinergic effects (except the “nonsedating” agents: astemizole, azelastine, cetirizine, desloratadine, fexofenadine, loratadine, and terfenadine). They may also stimulate or depress the CNS, and some agents (eg, diphenhydramine) have local anesthetic and membrane-depressant effects in large doses.
- B. **Pharmacokinetics.** Drug absorption may be delayed because of the pharmacologic effects of these agents on the gastrointestinal tract. Volumes of distribution are generally large (3–20 L/kg). Elimination half-lives are highly variable, ranging from 1–4 hours for diphenhydramine to 7–24 hours for many of the others. The half-life of astemizole is 7–19 days. (See also Table II–59, p 381.)

TABLE II-9. COMMON H₁ RECEPTOR ANTAGONIST ANTIHISTAMINES

Drug	Usual Duration of Action (hr)	Usual Single Adult Dose (mg)	Sedation
Ethanolamines			
Bromdiphenhydramine	4-6	12.5-25	+++
Carbinoxamine	3-4	4-8	++
Clemastine	10-12	0.67-2.68	++
Dimenhydrinate	4-6	50-100	+++
Diphenhydramine	4-6	25-50	+++
Diphenylpyraline	6-8	5	++
Doxylamine	4-6	25	+++
Phenyltoloxamine	6-8	50	+++
Ethylenediamines			
Pyrilamine	4-6	25-50	++
Thenyldiamine	8	10	++
Tripelennamine	4-6	25-50	++
Alkylamines			
Acrivastine	6-8	8	+
Brompheniramine	4-6	4-8	+
Chlorpheniramine	4-6	4-8	+
Dexbrompheniramine	6-8	2-4	+
Dexchlorpheniramine	6-8	2-4	+
Dimethindene	8	1-2	+
Pheniramine	8-12	25-50	+
Pyrrobutamine	8-12	15	+
Triprolidine	4-6	2.5	+
Piperazines			
Buclizine	8	50	
Cetirizine	24	5-10	+/-
Cinnarizine	8	15-30	+
Cyclizine	4-6	25-50	+
Flunarizine	24	5-10	+
Hydroxyzine	20-25	25-50	+++
Meclizine	12-24	25-50	+
Phenothiazines			
Methdilazine	6-12	4-8	+++
Promethazine	4-8	25-50	+++
Trimeprazine	6	2.5	+++
Others			
Astemizole	30-60 days	10	+/-
Azatidine	12	1-2	++
Cyproheptadine	8	2-4	+
Desloratadine	24	5	+/-
Fexofenadine	24	60	+/-
Loratadine	>24	10	+/-
Phenindamine	4-6	25	+/-
Terfenadine	12	60	+/-

- II. Toxic dose.** The estimated fatal oral dose of diphenhydramine is 20–40 mg/kg. In general, toxicity occurs after ingestion of 3–5 times the usual daily dose. Children are more sensitive to the toxic effects of antihistamines than adults.
- III. Clinical presentation**
- A.** An overdose results in many symptoms similar to anticholinergic poisoning: drowsiness, dilated pupils, flushed dry skin, fever, tachycardia, delirium, hallucinations, and myoclonic or choreoathetoid movements. Convulsions, rhabdomyolysis, and hyperthermia may occur with a serious overdose.
 - B. Massive diphenhydramine overdoses** have been reported to cause QRS widening and myocardial depression similar to tricyclic antidepressant overdoses (see p 90).
 - C. QT interval prolongation** and torsade-type atypical ventricular tachycardia (see p 14) have been associated with elevated serum levels of **terfenadine** or **astemizole**. Both of these drugs have been removed from the US market.
- IV. Diagnosis** is generally based on the history of ingestion and can usually be readily confirmed by the presence of typical anticholinergic syndrome. Comprehensive urine toxicology screening will detect most common antihistamines.
- A. Specific levels** are not generally available or useful.
 - B. Other useful laboratory studies** include electrolytes, glucose, arterial blood gases or pulse oximetry, and ECG monitoring (diphenhydramine, terfenadine, or astemizole).
- V. Treatment**
- A. Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat coma (p 19), seizures (p 22), hyperthermia (p 21), and atypical ventricular tachycardia (p 14) if they occur.
 3. Monitor the patient for at least 6–8 hours after ingestion. For terfenadine or astemizole, consider monitoring for at least 18–24 hours.
 - B. Specific drugs and antidotes.** There is no specific antidote for antihistamine overdose. As for anticholinergic poisoning (see p 84), **physostigmine** has been used for treatment of severe delirium or tachycardia. However, because antihistamine overdoses carry a greater risk for seizures, physostigmine is not routinely recommended. **Sodium bicarbonate** (see p 419), 1–2 mEq/kg IV, may be useful for myocardial depression and QRS interval prolongation after a massive diphenhydramine overdose.
 - C. Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal if available.
 2. **Hospital.** Administer activated charcoal. Consider gastric lavage for massive ingestions.
 - D. Enhanced elimination.** Hemodialysis, hemoperfusion, peritoneal dialysis, and repeat-dose activated charcoal are not effective in removing antihistamines.

DuBuske LM: Second-generation antihistamines: the risk of ventricular arrhythmias. *Clin Ther* 1999;21:281–295. [PMID: 10211532] (The newer agents loratadine, cetirizine, azelastine, and fexofenadine are not associated with torsade de pointes or other ventricular arrhythmias.)

High-dose loratadine exposure in a six-year-old child. *Vet Hum Toxicol* 2001;43(3):163–164. [PMID: 11383659] (A 300-mg overdose caused only minor elevation of blood pressure and heart rate.)

► ANTIMONY AND STIBINE

Peter Wald, MD, MPH

Antimony is widely used as a hardening agent in soft metal alloys and alloys of lead; for compounding rubber; as a major flame retardant component (5–20%) of plastics; and as a coloring agent in dyes, varnishes, paints, and glazes. Exposure to antimony dusts and fumes may also occur during mining and refining of ores and from the dis-

charge of firearms. Organic antimony compounds are used as antiparasitic drugs. **Stibine** (antimony hydride, SbH_3) is a colorless gas with the odor of rotten eggs that is produced as a by-product when antimony-containing ore or furnace slag is treated with acid.

- I. **Mechanism of toxicity.** The mechanism of antimony and stibine toxicity is not known. Because these compounds are chemically related to arsenic and arsine, their modes of action may be similar.

A. **Antimony** compounds probably act by binding to sulfhydryl groups and inactivating key enzymes.

B. **Stibine**, like arsine, may cause hemolysis. It is also an irritant gas.

II. Toxic dose

A. The lethal oral dose of **antimony** in mice is 100 mg/kg; at these doses mice developed eosinophilia and cardiac failure. The recommended workplace limit (ACGIH TLV-TWA) for antimony is 0.5 mg/m³ as an 8-hour time-weighted average. The air level considered immediately dangerous to life or health (IDLH) is 50 mg/m³.

B. The recommended workplace limit (ACGIH TLV-TWA) for **stibine** is 0.1 ppm as an 8-hour time-weighted average. The air level considered immediately dangerous to life or health (IDLH) is 5 ppm.

III. Clinical presentation

A. **Acute ingestion of antimony** causes nausea, vomiting, and diarrhea (often bloody). Hepatitis and renal insufficiency may occur. Death is rare if the patient survives the initial gastroenteritis.

B. **Acute stibine inhalation** causes acute hemolysis, resulting in anemia, jaundice, hemoglobinuria, and renal failure.

C. **Chronic exposure to antimony dusts and fumes** in the workplace is the most common type of exposure and may result in headache, anorexia, pneumonitis, peptic ulcers, and dermatitis (antimony spots). Sudden death presumably resulting from a direct cardiotoxic effect has been reported in workers exposed to antimony trisulfide. Antimony trioxide is a suspected carcinogen (IARC 2B).

IV. Diagnosis is based on a history of exposure and typical clinical presentation.

A. **Specific levels.** Urine antimony levels are normally below 2 mcg/L. Serum and whole-blood levels are not reliable and are no longer used. Urine concentrations correlate poorly with workplace exposure, but exposure to air concentrations greater than the TLV-TWA will increase urinary levels. Urinary antimony is increased after firearm discharge exposure. There is no established toxic antimony level after stibine exposure.

B. **Other useful laboratory studies** include CBC, plasma-free hemoglobin, electrolytes, BUN, creatinine, urinalysis for free hemoglobin, liver transaminases, bilirubin, and prothrombin time (PT).

V. Treatment

A. Emergency and supportive measures

1. **Antimony.** Large-volume intravenous fluid resuscitation may be necessary for shock caused by gastroenteritis (see p 16).

2. **Stibine.** Blood transfusion may be necessary after massive hemolysis. Treat hemoglobinuria with fluids and bicarbonate as for rhabdomyolysis (see p 27).

B. **Specific drugs and antidotes.** There is no specific antidote. BAL (dimercaprol) and penicillamine are not effective chelators for antimony, nor are they expected to be effective for stibine.

C. Decontamination (see p 46)

1. **Inhalation.** Remove the patient from exposure, and give supplemental oxygen if available. Protect rescuers from exposure.

2. **Ingestion** of antimony salts

a. **Prehospital.** Activated charcoal is probably not effective. Ipecac-induced vomiting may be useful for initial treatment at the scene if it can be given within a few minutes of exposure.

- b. Hospital.** Consider gastric lavage, depending on the dose and time since ingestion.
- D. Enhanced elimination.** Hemodialysis, hemoperfusion, and forced diuresis are **not** effective at removing antimony or stibine. Exchange transfusion may be effective in treating massive hemolysis caused by stibine.

NIOSH documentation for antimony level considered IDLH: <http://www.cdc.gov/niosh/idlh/7440360.html>.

NIOSH documentation for stibine level considered IDLH: <http://www.cdc.gov/niosh/idlh/7803523.html>.

► ANTINEOPLASTIC AGENTS

Susan Kim, PharmD

Because of the inherently cytotoxic nature of most chemotherapeutic antineoplastic agents, overdoses are likely to be extremely serious. These agents are classified into seven categories (Table II–10). Other than iatrogenic errors, relatively few acute overdoses have been reported for these agents.

- I. Mechanism of toxicity.** In general, toxic effects are extensions of the pharmacologic properties of these drugs.
 - A. Alkylating agents.** These drugs attack nucleophilic sites on DNA, resulting in alkylation and cross-linking and thus inhibiting replication and transcription. Binding to RNA or protein moieties appears to contribute little to cytotoxic effects.
 - B. Antibiotics.** These drugs intercalate within base pairs in DNA, inhibiting DNA-directed RNA synthesis. Another potential mechanism may be the generation of cytotoxic free radicals.
 - C. Antimetabolites.** These agents interfere with DNA synthesis at various stages. For example, methotrexate binds reversibly to dihydrofolate reductase, preventing synthesis of purine and pyrimidine nucleotides.
 - D. Hormones.** Steroid hormones regulate the synthesis of steroid-specific proteins. The exact mechanism of antineoplastic action is unknown.
 - E. Mitotic inhibitors.** These agents act in various ways to inhibit orderly mitosis, thereby arresting cell division.
 - F. Topoisomerase inhibitors** inhibit topoisomerase I, an enzyme that relieves torsional strain during DNA replication. The cleavable complex normally formed between DNA and topoisomerase I is stabilized by these drugs, resulting in breaks in single-stranded DNA.
 - G. Monoclonal antibodies** target antigens specific to or overexpressed in cancerous cells. The antibodies may be directly cytotoxic or may be used to deliver radionuclides or cytotoxins to the target cells.
 - H. Others.** The cytotoxic actions of other antineoplastic drugs result from a variety of mechanisms, including blockade of protein synthesis and inhibition of hormone release.
- I. Pharmacokinetics.** Most oral antineoplastic agents are readily absorbed, with peak levels reached within 1–2 hours of ingestion. Due to rapid intracellular incorporation and the delayed onset of toxicity, pharmacokinetic values are usually of little utility in managing acute overdose. (See also Table II–59.)
- II. Toxic dose.** Because of the highly toxic nature of these agents (except for hormones), exposure to even therapeutic amounts should be considered potentially serious.
- III. Clinical presentation.** The organ systems affected by the various agents are listed in Table II–10. The most common sites of toxicity are the hematopoietic and gastrointestinal systems.
 - A. Leukopenia** is the most common manifestation of bone marrow depression. Thrombocytopenia and anemia may also occur. Death may result from over-

TABLE II-10. COMMON ANTINEOPLASTIC AGENTS AND THEIR TOXICITIES

Drug	Major Site(s) of Toxicity ^a	Comments
Alkylating agents		
Busulfan	D+, En+, G+, M+, N+, P++	Acute overdose of 2.4 g was fatal in a 10-year-old. High doses can cause coma, seizures. Hemodialysis may be effective. Pulmonary fibrosis, adrenal insufficiency with chronic use.
Carmustine (BCNU)	D+, Ex+, G+, H+, M+, P+	Flushing, hypotension, and tachycardia with rapid IV injection.
Chlorambucil	D+, G+, H+, M+, N++	Seizures, confusion, coma reported after overdose. Acute ODs of 1.5–6.8 mg/kg in children caused seizures up to 3–4 hours post ingestion. Not dialyzable.
Cyclophosphamide	Al++, C+, D+, En+, G++, M++, R+	Hemodialysis effective. Acetylcysteine and 2-mercaptoethanesulfonate have been used investigationaly to reduce hemorrhagic cystitis.
Dacarbazine	Al+, An+, En+, G++, H+, M+, N+, Ex±	May produce flu-like syndrome. Photosensitivity reported.
Ifosfamide	M++, N+, Al++, G+, R+	Urotoxic. Hemorrhagic cystitis, somnolence, confusion, hallucinations, status epilepticus, coma seen during therapy. Combined hemodialysis and hemoperfusion reduced serum levels by 84%.
Lomustine (CCNU)	Al+, G+, H+, M+, P+	Thrombocytopenia, leukopenia, liver and lymph node enlargement after overdose.
Mechlorethamine	D+, G++, M++, N+, Ex+	Lymphocytopenia may occur within 24 hours. Watch for hyperuricemia.
Melphalan	An+, G+, M+	Hemodialysis may be effective although of questionable need (normal half-life only 90 minutes).
Thiotepa	An+, G++, M++	Bone marrow suppression usually very severe.
Temozolomide	G+, M+, N+	Relatively benign safety profile.
Antibiotics		
Bleomycin	An++, D++, G+, P++	Pulmonary fibrosis with chronic use. Febrile reaction in 20–25% of patients.
Dactinomycin	Al++, D+, G++, M++, Ex++	Severe inflammatory reaction may occur at previously irradiated sites. Highly corrosive to soft tissue.
Daunorubicin	Al++, An+, C++, G++, M++, Ex++	Congestive cardiomyopathy may occur after total cumulative dose > 600 mg/m ² .

(continued)

TABLE II-10. COMMON ANTINEOPLASTIC AGENTS AND THEIR TOXICITIES (CONTINUED)

Drug	Major Site(s) of Toxicity ^a	Comments
Doxorubicin	Al++, An+, C++, D+, Ex++, G++, M++, Ex++	Cardiotoxicity and cardiomyopathy may occur after total cumulative dose > 550 mg/m ² . Arrhythmias after acute overdose. Hemoperfusion may be effective. Dexrazoxane is usually given for cardioprotection.
Epirubicin	C++, Ex++, G+, M++	Death from multiorgan failure reported in a 63-year-old woman after a single 320-mg/m ² dose. Risk of congestive heart failure increases steeply after cumulative dose of 900 mg/m ² .
Idarubicin	C++, G+, M++, Ex++	Congestive heart failure, acute life-threatening arrhythmias may occur.
Mitomycin	Al+, D+, G++, H+, M+, P+, R+, Ex++	Hemolytic uremic syndrome reported with therapeutic doses.
Mitoxantrone	An+, C+, G++, M++	Four reported overdosed patients died from severe leukopenia and infection.
Pentostatin	D+, G+, M+, N++, R++	Central nervous system depression, convulsions, coma seen at high doses.
Plicamycin (mithramycin)	An+, D+, G++, H++, M++, N+, Ex+	Coagulopathy, electrolyte disturbances may occur. Check calcium frequently.
Valrubicin	D+ (bladder irrigation), M+	Synthetic analog of doxorubicin; used intravesically for bladder cancer.
Antimetabolites		
Capecitabine	D+, G+, M+	Prodrug; converted to 5-fluorouracil.
Cladribine	M++, N++, R++	Irreversible paraparesis/quadruparesis seen in high doses.
Cytarabine	An+, En+, G+, H+, M+, P+, N+	"Cytarabine syndrome": fever, myalgia, bone pain, rash, malaise.
Floxuridine	Al+, G++, M++	
Fludarabine	G+, M++, N++, R+	Blindness, coma, death at high doses.
5-Fluorouracil	Al+, C+, D+, G++, M++, N+	Acute cerebellar syndrome seen. Coronary vasospasm with angina may occur.
Gemcitabine	An+, D+, H+, M++, P+, R+	Can cause bronchospasm.
6-Mercaptopurine	G+, H++, M+	Hemodialysis removes drug but of questionable need (half-life 20–60 minutes).
Methotrexate	Al+, D+, G++, H+, M++, N+, P+, R+	Peak serum level 1–2 hours after oral dose. Folinic acid (leucovorin; see p 460) is specific antidote. Hemoperfusion questionably effective. Urinary alkalinization and repeat dose charcoal may be helpful.
6-Thioguanine	G+, H+, M+, R+	Hemodialysis probably ineffective owing to rapid intracellular incorporation.

Hormones**Androgens**

Testolactone	En±, G±	Toxicity unlikely after single acute overdose.
--------------	---------	--

Antiandrogens

Flutamide, bicalutamide, nilutamide	G+	Gynecomastia. Aniline metabolite of flutamide has caused methemoglobinemia (see p 261). Nilutamide 13-g ingestion resulted in no evidence of toxicity.
-------------------------------------	----	--

Estrogens

Diethylstilbestrol	En±, G±	Possible carcinogenic effect on fetus if taken during early pregnancy.
--------------------	---------	--

Estramustine	En±, G±, H±, M±	Has both weak estrogenic and alkylating activity.
--------------	-----------------	---

Antiestrogens

Tamoxifen, toremifene, fulvestrant	Al±, D±, En±, G±	Acute toxic effects unlikely. Tremors, hyperreflexia, unsteady gait, QT prolongation with high doses of tamoxifen.
------------------------------------	------------------	--

Progestins

Medroxyprogesterone, megestrol	An±, En±, G±	Acute toxic effects unlikely. May induce porphyria in susceptible patients.
--------------------------------	--------------	---

Aromatase Inhibitors

Anastrozole, exemestane, letrozole	G±	Acute toxic effects unlikely.
------------------------------------	----	-------------------------------

Gonadotropin-Releasing Hormone Analogs

Leuprolide, goserelin, triptorelin	En+	Acute toxic effects unlikely. Initial increase in luteinizing hormone, follicle-stimulating hormone levels.
------------------------------------	-----	---

Mitotic inhibitors

Docetaxel	An+, D+, M++, N+	Severe fluid retention in 6% of patients.
-----------	------------------	---

Etoposide	An+, G+, M++	Myelosuppression major toxicity. Dystonic reaction reported.
-----------	--------------	--

Paclitaxel	An++, C+, M+, N+	Severe hypersensitivity reactions, including death, reported. Hypotension, bradycardia, ECG abnormalities, conduction abnormalities may occur. Fatal myocardial infarction 15 h into infusion reported.
------------	------------------	---

(continued)

TABLE II-10. COMMON ANTINEOPLASTIC AGENTS AND THEIR TOXICITIES (CONTINUED)

Drug	Major Site(s) of Toxicity ^a	Comments
Teniposide	An+, G+, M++, Ex+	One report of sudden death from hypotension, cardiac arrhythmias. Hypotension from rapid IV injection.
Vinblastine	G+, M++, N+, Ex++	Myelosuppression, ileus, syndrome of inappropriate antidiuretic hormone reported after overdose. Fatal if given intrathecally.
Vincristine sulfate	G+, M±, N++, Ex++	Delayed (up to 9 days) seizures, delirium, coma reported after overdoses. Fatal if given intrathecally. Glutamic acid 500 mg TID orally may reduce the incidence of neurotoxicity.
Vinorelbine	G+, M++, N+, Ex++	Severe granulocytopenia.
Topoisomerase inhibitors		
Irinotecan	G++, M+	Severe diarrhea. Cholinergic syndrome during infusion.
Topotecan	G+, M++	Severe thrombocytopenia, anemia common.
Monoclonal antibodies		
Alemtuzumab	An+, D+, G+, M++	Can cause severe prolonged lymphopenia. Serious risk of fatal bacterial or opportunistic infections.
Gemtuzumab ozogamicin	An+, H+, M++	Associated with hepatic veno-occlusive disease.
Ibritumomab tiuxetan	An++, M++, G+	Use in radioimmunotherapy. Severe, fatal infusion reactions reported.
Rituximab	An++, C+, D++, M+, P+, R++	Severe, fatal hypersensitivity reaction possible. Tumor lysis syndrome has caused acute renal failure. Potentially fatal mucocutaneous reactions reported.
Trastuzumab	An++, C++, P+	Can precipitate congestive heart failure. Severe, fatal hypersensitivity and infusion reactions reported.
Miscellaneous		
Aldesleukin (Interleukin 2)	C++, G+, H+, M+, N+, P+, R+	Commonly causes capillary leak syndrome resulting in severe hypotension.
Altretamine	G+, N+, M+	Reversible peripheral sensory neuropathy.

Asparaginase	An++, En+, G+, H++, N++, R+	Bleeding diathesis, hyperglycemia, pancreatitis.
BCG (Intravesical)	G+	Attenuated <i>Mycobacterium bovis</i> . Bladder irritation common. Risk of sepsis in immunocompromised patients.
Bexarotene	D+, G+, M+	Serious lipid and thyroid abnormalities reported.
Carboplatin	An+, G++, M++, R+	Peripheral neuropathy in 4% of patients.
Cisplatin	An+, G++, M+, N+, P+, R++	Ototoxic, nephrotoxic. Good hydration essential. Hemodialysis not effective. Amifostine and sodium thiosulfate (experimentally) have been used to reduce cytotoxic effects.
Denileukin	An+, C+, D+, G+, N+	Can cause vascular leak syndrome (hypoalbuminemia, edema, hypotension).
Hydroxyurea	D+, G+, M++	Leukopenia, anemia more common than thrombocytopenia. Peak serum level within 2 h of oral dose.
Imatinib	G+, H+, M+	Fluid retention and edema, and muscle cramps.
Interferon alpha 2a	G+, H+, M++, N+	Flu-like symptoms common. Severe hypotension from inadvertent IV reported.
Interferon alpha 2b	G+, M+	Flu-like symptoms common.
Levamisole	G+, M+, N+	May have nicotinic and muscarinic effects at cholinergic receptors. Gastroenteritis, dizziness, headache after 2.5-mg/kg dose reported. Fatality reported after ingestion of 15 mg/kg in a 3-year-old and 32 mg/kg in an adult. Disulfiram-like ethanol interaction may also occur.
Mitotane	Al+, D+, En++, G++, N++	Adrenal suppression; glucocorticoid replacement essential during stress.
Pegaspargase	An++, G+, H+, N+	Bleeding diathesis.
Porfimer	D+, G+	Used in conjunction with phototherapy: risk of photosensitivity.
Procarbazine hydrochloride	An+, D+, En+, G++, M++, N++	Monoamine oxidase inhibitor activity. Disulfiram-like ethanol interaction.
Streptozocin	En+, G+, H+, M+, R++	Destroys pancreatic beta islet cells; may produce acute diabetes mellitus. Niacinamide (see p 475) may be effective in preventing islet cell destruction. Renal toxicity in two-thirds of patients.
Tretinoin	C+, D+, G+, N+, P+	Retinoic acid–APL syndrome seen in ~25% of patients with acute promyelocytic leukemia: fever, dyspnea, pulmonary infiltrates, and pleural or pericardial effusions.

^aAl = alopecia; An = anaphalaxis, allergy, or drug fever; C = cardiac; D = dermatologic; En = endocrine; Ex = extravasation risk; G = gastrointestinal; H = hepatic; M = myelosuppressive; N = neurologic; P = pulmonary; R = renal; + = mild to moderate severity; ++ = severe toxicity; ± = minimal.

whelming infections or hemorrhagic diathesis. With alkylating agents, lowest blood counts occur 1–4 weeks after exposure, whereas with antibiotics, antimetabolites, and mitotic inhibitors, the lowest blood counts occur 1–2 weeks after exposure.

B. Gastrointestinal toxicity is also very common. Nausea, vomiting, and diarrhea often accompany therapeutic administration, and severe ulcerative gastroenteritis and extensive fluid loss may occur.

C. Extravasation of some antineoplastic drugs at the intravenous injection site may cause severe local injury, with skin necrosis and sloughing.

IV. Diagnosis is usually based on the history. Because some of the most serious toxic effects may be delayed until several days after exposure, early clinical symptoms and signs may not be dramatic.

A. Specific levels. Not generally available. For methotrexate, see Table III–7, p 461.

B. Other useful laboratory studies include CBC with differential, platelet count, electrolytes, glucose, BUN and creatinine, liver enzymes, and prothrombin time (PT). ECG may be indicated for cardiotoxic agents, and pulmonary function tests are indicated for agents with known pulmonary toxicity.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and arrhythmias (pp 10–15) if they occur.
3. Treat nausea and vomiting with metoclopramide (see p 467) and fluid loss caused by gastroenteritis with intravenous crystalloid fluids.
4. **Bone marrow depression** should be treated with the assistance of an experienced hematologist or oncologist.
5. **Extravasation.** Immediately stop the infusion and withdraw as much fluid as possible by negative pressure on the syringe. Then give the following specific treatment:

a. Dactinomycin, daunorubicin, doxorubicin, idarubicin, mitomycin-C, mitoxantrone, and plicamycin. Apply ice compresses to the extravasation site for 15 minutes 4 times daily for 3 days. Topical application of dimethyl sulfoxide (DMSO) may be beneficial (commercially available 50% solution is less concentrated than those used in experimental studies, but may be tried). There is no justification for injection of hydrocortisone or sodium bicarbonate.

b. Mechlorethamine (and concentrated **dacarbazine** and **cisplatin**). Infiltrate the site of extravasation with 10 mL of sterile 2.5% sodium thiosulfate (dilute 1 mL of 25% thiosulfate with sterile water to a volume of 10 mL); apply ice compresses for 6–12 hours.

c. Etoposide, paclitaxel, vincristine, or vinblastine. Place a heating pad over the area and apply heat intermittently for 24 hours; elevate the limb. Local injection of hyaluronidase (150–900 units) may be beneficial. Do not use ice packs.

B. Specific drugs and antidotes. Very few specific treatments or antidotes are available (Table II–10).

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal, if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary after a small ingestion if activated charcoal can be given promptly.

D. Enhanced elimination. Because of the rapid intracellular incorporation of most agents, dialysis and other extracorporeal removal procedures are generally not effective (see Table II–10 for exceptions).

Albanell J, Baselga J: Systemic therapy emergencies. *Semin Oncol* 2000;27(3):347–361. [PMID: 10864222] (Medical management of chemotherapeutic drug extravasation and hypersensitivity reactions.)

► ANTIPSYCHOTIC DRUGS

Grant D. Lackey, PharmD, PhD

Phenothiazines, butyrophenones, and several other related and newer drugs are widely used to treat psychosis and agitated depression. In addition, some of these drugs (eg, prochlorperazine, promethazine, and droperidol) are used as antiemetic agents. Suicidal overdoses are common, but because of the high toxic-therapeutic ratio, acute overdose seldom results in death. A large number of newer agents referred to as “atypical antipsychotics” have been developed. These drugs have generally less effect on CNS dopamine receptors and mixed effects on serotonin and norepinephrine activity. Table II–11 describes available antipsychotic agents.

TABLE II–11. COMMON ANTIPSYCHOTIC DRUGS

Drug	Type ^a	Usual Adult Daily Dose (mg)	Toxicity ^b
Chlorpromazine	P	200–2000	A, E, H, Q
Chlorprothixene	T	75–200	E
Clozapine	D	100–900	A, H
Droperidol	B	2–10	E, Q
Ethopropazine	P	50–400	A, H
Fluphenazine	P	2.5–20	E, A
Haloperidol	B	1–100	E, Q
Loxapine	D	60–100	E
Mesoridazine	P	150–400	A, H, Q
Molindone	O	50–225	E
Olanzapine	D	5–20	A, E, H
Perphenazine	P	10–30	E
Pimozide	O	2–10	E, Q
Prochlorperazine ^c	P	15–40	E
Promethazine ^c	P	25–200	A, E
Quetiapine	D	150–750	A, E, H, Q
Risperidone	O	4–16	E, H, Q
Thioridazine	P	150–300	A, H, Q
Thiothixene	T	5–60	E
Trifluoperazine	P	1–40	E
Trimethobenzamide ^c	O	600–1000	A, E
Ziprasidone	O	60–160	A, E, H, Q

^aP = Phenothiazine; T = Thiothixene; B = Butyrophenone; D = Dibenzodiazepine; O = Other.
^bE = Extrapyramidal reactions; A = Anticholinergic effects; H = Hypotension; Q = QT interval prolongation.
^cUsed primarily as an antiemetic.

- I. Mechanism of toxicity.** A variety of pharmacologic effects are responsible for toxicity involving primarily the cardiovascular and central nervous systems.
- A. Cardiovascular.** Anticholinergic effects may produce tachycardia. Alpha-adrenergic blockade may cause orthostatic hypotension. With very large overdoses of some agents, quinidine-like membrane-depressant effects on the heart may occur. Many agents can cause QT prolongation and torsade de pointes (see p 14).
- B. Central nervous system.** Centrally mediated sedation and anticholinergic effects contribute to CNS depression. Alpha-adrenergic blockade causes small pupils, despite anticholinergic effects on other systems. Extrapyramidal dystonic reactions are relatively common with therapeutic doses (especially of butyrophenones) and are probably caused by central dopamine receptor blockade. The seizure threshold may be lowered by unknown mechanisms. Temperature regulation is also disturbed, resulting in poikilothermia.
- C. Pharmacokinetics.** These drugs have large volumes of distribution ($V_d = 10\text{--}30\text{ L/kg}$), and most have long elimination half-lives (eg, chlorpromazine = 18–30 hours). Elimination is largely by hepatic metabolism. See Table II–59, p 381.
- II. Toxic dose.** Extrapyramidal reactions, anticholinergic side effects, and orthostatic hypotension are often seen with therapeutic doses. Tolerance to the sedating effects of the antipsychotics is well described, and patients on chronic therapy may tolerate much larger doses than other persons.
- A.** Typical daily doses are given in Table II–11.
- B.** The toxic dose after acute ingestion is highly variable. Serious CNS depression and hypotension may occur after ingestion of 200–1000 mg of chlorpromazine in children or 3–5 g in adults.
- III. Clinical presentation.** Major toxicity is manifested in the cardiovascular and central nervous systems. Also, anticholinergic intoxication (see p 84) may occur as a result of ingestion of benztropine (Cogentin) or other co-administered drugs.
- A. Mild intoxication** causes sedation, small pupils, and orthostatic hypotension. Anticholinergic manifestations include dry mouth, absence of sweating, tachycardia, and urinary retention. Paradoxically, clozapine causes hypersalivation through an unknown mechanism.
- B. Severe intoxication** may cause coma, seizures, and respiratory arrest. The ECG may show QTc interval prolongation and occasionally QRS prolongation (particularly with thioridazine [Mellaril]). Hypothermia or hyperthermia may occur. Clozapine can cause a prolonged confusional state and rarely cardiac toxicity.
- C. Extrapyramidal** dystonic side effects of therapeutic doses include torticollis, jaw muscle spasm, oculogyric crisis, rigidity, bradykinesia, and pill-rolling tremor. These effects are more common with butyrophenones and high-potency phenothiazines.
- D.** Patients on chronic antipsychotic medication may develop the **neuroleptic malignant syndrome** (see p 21) characterized by rigidity, hyperthermia, sweating, lactic acidosis, and rhabdomyolysis.
- E.** Clozapine use has been associated with agranulocytosis.
- IV. Diagnosis** is based on a history of ingestion and findings of sedation, small pupils, hypotension, and QT interval prolongation. Dystonias in children should always suggest the possibility of antipsychotic exposure, often as a result of intentional administration by parents. Phenothiazines are occasionally visible on plain abdominal x-rays (see Table I–35, p 46).
- A. Specific levels.** Quantitative blood levels are not routinely available and do not help in diagnosis or treatment. Qualitative screening may easily detect phenothiazines in urine or gastric juice, but butyrophenones such as haloperidol are usually not included in toxicologic screens (see Table I–32, p 42).
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, CPK, arterial blood gases or oximetry, abdominal x-ray (to look for radiopaque pills), and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and hyperthermia (p 21) if they occur. Due to the alpha-blocking properties of many of these agents, norepinephrine may be more effective than other vasopressors.
3. Monitor vital signs and ECG for at least 6 hours, and admit the patient for at least 24 hours if there are signs of significant intoxication. Children with antipsychotic intoxication should be evaluated for possible intentional abuse.

B. Specific drugs and antidotes. There is no specific antidote.

1. **Dystonic reactions.** Give **diphenhydramine**, 0.5–1 mg/kg IM or IV (see p 436) or **benztropine** (p 418).
2. **QRS interval prolongation.** Treat quinidine-like cardiotoxic effects with **bicarbonate**, 1–2 mEq/kg IV (see p 419).
3. **QTc prolongation.** Normalize serum potassium and magnesium, if low. Treat torsade de pointes (see p 14) if it occurs.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. Owing to extensive tissue distribution, these drugs are not effectively removed by dialysis or hemoperfusion. Repeat-dose activated charcoal has not been evaluated.

Burns MJ: The pharmacology and toxicology of atypical antipsychotic agents. *J Toxicol Clin Toxicol* 2001;39(1):1–14. [PMID: 11327216] (Review of clozapine, olanzapine, quetiapine, and risperidone.)

Haddad PM, Anderson IM: Antipsychotic-related QTc prolongation, torsades de pointes and sudden death. *Drugs* 2002;62(11):1649–1671. [PMID: 12109926] (In the UK, sertindole and droperidol are no longer on the market, and restricted labeling was introduced for thioridazine and pimozide. Among currently available agents in the UK, thioridazine and ziprasidone are associated with the greatest QTc prolongation.)

► ANTISEPTICS AND DISINFECTANTS

Kerry Schwarz, PharmD

Antiseptics are applied to living tissue to kill or prevent the growth of microorganisms. **Disinfectants** are applied to inanimate objects to destroy pathogenic microorganisms. Despite their unproved worth, they are widely used in the household, food industry, and hospitals. This chapter describes toxicity caused by **chlorhexidine**, **glutaraldehyde**, **hexylresorcinol**, **hydrogen peroxide**, **ichthammol**, and **potassium permanganate**. These agents are often used as dilute solutions which usually cause little or no toxicity. Hexylresorcinol is commonly found in throat lozenges. Ichthammol is found in many topical salves. Descriptions of the toxicity of other antiseptics and disinfectants can be found elsewhere in this book, including the following: hypochlorite (see p 162), iodine (p 226), isopropyl alcohol (p 234), mercurochrome (p 254), phenol (p 302), and pine oil (p 219).

I. Mechanism of toxicity

1. **A. Chlorhexidine** is commonly found in dental rinses, mouthwashes, and a variety of cosmetics. Exposure to a concentration less than 0.14% is not likely to cause more than minor irritation, but higher concentrations have caused corrosive injury.

- B. **Glutaraldehyde** is used to disinfect medical equipment, as a tissue preservative, topically as an antifungal, and is found in some x-ray solutions. It is highly irritating to the skin and respiratory tract.
- C. **Hexylresorcinol** is related to phenol but is much less toxic, although alcohol-based solutions possess vesicant properties.
- D. **Hydrogen peroxide** is an oxidizing agent, but it is very unstable and readily breaks down to oxygen and water. Generation of oxygen gas in closed body cavities can potentially cause mechanical distension resulting in gastric or intestinal perforation, as well as venous or arterial gas embolization.
- E. **Ichthammol** (ichthyol, ammonium ichthosulfonate) contains about 10% sulfur in the form of organic sulfonates, and is keratolytic to tissues.
- F. **Potassium permanganate** is an oxidant, and the crystalline form or concentrated solutions are corrosive.

II. Toxic dose

- A. **Chlorhexidine** ingestions of less than 4% have not caused tissue damage. Ingestion of 150 mL of 20% solution caused esophageal damage and hepatic injury.
- B. The lethal dose of **glutaraldehyde** is estimated to be from 50 mg/kg to 5 g/kg. Topical application of 10% solutions can cause dermatitis.
- C. **Hexylresorcinol** is used in some anthelmintics, in doses of 400 mg (for children aged 1–7 years) to 1 g (older children and adults). Most lozenges contain only about 2–4 mg.
- D. **Hydrogen peroxide** for household use is available in 3–5% solutions and it causes only mild throat and gastric irritation with ingestion of less than 1 oz. Concentrations above 10% are found in some hair-bleaching solutions and are potentially corrosive. Most reported deaths have been associated with ingestion of undiluted 35% hydrogen peroxide, sold in some health food stores as “hyperoxygen therapy.”
- E. **Potassium permanganate** solutions of greater than 1:5000 strength may cause corrosive burns.

III. Clinical presentation.

Most low-concentration antiseptic ingestions are benign, and mild irritation is self-limited. Spontaneous vomiting and diarrhea may occur, especially after a large-volume ingestion.

- A. Exposure to **concentrated** antiseptic solutions may cause corrosive burns on the skin and mucous membranes, and oropharyngeal, esophageal, or gastric injury may occur. Glottic edema has been reported after ingestion of concentrated potassium permanganate.
- B. Permanganate may also cause **methemoglobinemia** (see p 261).
- C. **Hydrogen peroxide** ingestion may cause gastric distension and, rarely, perforation. Severe corrosive injury and **air emboli** have been reported with the concentrated forms and may be caused by the entry of gas through damaged gastric mucosa or oxygen gas liberation within the venous or arterial circulation.

IV. Diagnosis

is based on a history of exposure and the presence of mild gastrointestinal upset or frank corrosive injury. Solutions of potassium permanganate are dark purple, and skin and mucous membranes are often characteristically stained.

- A. **Specific levels.** Drug levels in body fluids are not generally useful or available.
- B. **Other useful laboratory studies** include electrolytes, glucose, methemoglobin level (for potassium permanganate exposure), and upright chest x-ray (for suspected gastric perforation).

V. Treatment

A. Emergency and supportive measures

1. In patients who have ingested concentrated solutions, monitor the airway for swelling and intubate if necessary.
2. Consult a gastroenterologist for possible endoscopy after ingestions of corrosive agents such as concentrated hydrogen peroxide or potassium

permanganate. Most ingestions are benign, and mild irritation is self-limited.

3. Consider **hyperbaric oxygen** treatment for gas emboli associated with concentrated peroxide ingestion.

B. Specific drugs and antidotes. No specific antidotes are available for irritant or corrosive effects. If **methemoglobinemia** occurs, administer methylene blue (see p 466).

C. Decontamination (see p 46)

1. **Ingestion** of concentrated corrosive agents (see also p 157)

- a. Dilute immediately with water or milk.

- b. Do **not** induce vomiting because of the risk of corrosive injury. Perform gastric lavage cautiously.

- c. Activated charcoal and cathartics are not effective.

2. **Eyes and skin.** Irrigate the eyes and skin with copious amounts of tepid water. Remove contaminated clothing.

D. Enhanced elimination. Enhanced elimination methods are neither necessary nor effective.

► ANTIVIRAL AND ANTIRETROVIRAL AGENTS

Olga F. Woo, PharmD

Human immunodeficiency virus (HIV) infection was first reported in 1981. The search for effective anti-HIV treatment began with zidovudine (AZT) in 1987 as a single-agent regimen. In 1994 the first protease inhibitor, saquinavir, was introduced. More agents and different classes of antiretroviral agents were later developed (Table II–12). The use of combinations of antiviral drugs with different mechanisms of action in highly active antiretroviral therapy (HAART) regimens has dramatically improved survival in patients with HIV infection. Acute single ingestions are infrequent, and toxicity has been generally mild. Chronic toxicity, however, commonly occurs.

- I. Mechanism of toxicity.** The mechanism underlying toxic effects varies depending on the agent, and is usually an extension of its pharmacologic effect.

- A. Neurotoxicity** may be the result of inhibition of mitochondrial DNA polymerase and altered mitochondrial cell function.

- B. Hepatic steatosis, severe lactic acidosis, and lipodystrophy** may be due to inhibition of DNA polymerase-gamma, which depletes mitochondrial DNA, causing mitochondrial dysfunction. Mitochondrial RNA formation may also be inhibited.

- C.** Acyclovir crystal deposition in the tubular lumen leading to an obstructive nephropathy may cause **acute renal failure**. Indinavir is poorly water soluble and can precipitate in the kidney, causing kidney stones and interstitial nephritis.

- D.** Other serious toxicities that develop after chronic use of many of these agents include bone marrow depression, diabetes mellitus, hepatotoxicity, lactic acidosis, lipodystrophy, lipatrophy, pancreatitis, peripheral neuropathy, renal failure, and seizures.

TABLE II-12. ANTIVIRAL AND ANTIRETROVIRAL DRUGS

Drug	Half-Life	Toxic Dose or Serum Level	Toxicity
Antih herpes drugs			
Acyclovir	2.5–3.3 h	Chronic	High-dose chronic therapy has caused crystalluria and renal failure, leukopenia. Coma, seizures, renal failure after large acute overdoses. Hallucinations and confusion after IV administration.
Cidofovir		16.3 and 17.4 mg/kg (case reports)	No renal dysfunction after treatment with probenecid and IV hydration.
Famciclovir	2–2.3 h		Prodrug metabolized to active penciclovir.
Foscarnet	3.3–4 h	1.14–8 times recommended dose (average 4 times)	Seizures, renal impairment. One patient had seizures and died after receiving 12.5 g daily for 3 days.
Ganciclovir	3.5 h (IV) 4.8 h (oral)	Adults: 5–7 g or 25 mg/kg IV	Neutropenia, thrombocytopenia, pancytopenia, increased serum creatinine; 9 mg/kg IV caused a seizure; 10 mg/kg IV daily caused hepatitis. Children: 1 g instead of 31 mg in a 21-month-old had no toxic effect; an 18-month-old received 60 mg/kg IV, was treated with exchange transfusion, and had no effect; a 4-month-old received 500 mg, was treated with peritoneal dialysis, and had no effect; 40 mg in a 2-kg infant caused hepatitis.
Penciclovir			Extensive intracellular metabolism.
Trifluridine		15–30 mg/kg IV	Reversible bone marrow toxicity reported after 3–5 courses of IV treatment. Systemic absorption is negligible after ophthalmic instillation. Ingestion of contents of one bottle (7.5 mL, 75 mg) unlikely to cause any adverse effects.
Valacyclovir			Prodrug promptly converted to acyclovir.
Vidarabine	Rapid deamination to ara-hypoxanthine metabolite whose half-life is 2.4–3.3 h	Chronic 1–20 mg/kg/day IV for 10–15 days	Nausea, vomiting, diarrhea, dizziness, ataxia, tremor, confusion, hallucinations, psychosis; decreased Hct, Hgb, WBC, platelets; increased AST, ALT, LDH. Poorly absorbed orally—no toxicity expected if one tube (3.5 g, 105 mg) ingested.
Nucleoside reverse transcriptase inhibitors (NRTI)			Lactic acidosis, mitochondrial toxicity, hepatotoxicity.
Abacavir	1.54 ± 0.63 h	Chronic	Diarrhea, nausea, vomiting; hypersensitivity (fatal reactions reported); perioral paresthesias.
Didanosine (ddI)	1.5 ± 0.4 h	Chronic	Diarrhea, pancreatitis, peripheral neuropathy, salt overload with buffered product.
Lamivudine (3TC)	5–7 h	Chronic	Headaches, nausea.

Stavudine (d4T)	1.15 h IV 1.44 h PO	Chronic	Hepatic steatosis, lactic acidosis, peripheral neuropathy.
Tenofovir ^a	1–4 h	Chronic	Diarrhea, flatulence, nausea, vomiting.
Zalcitabine (ddC)	1–3 h	Chronic	Oral ulcers, peripheral neuropathy.
Zidovudine (AZT)	0.5–1.5 h	Chronic	Anemia, fatigue, headaches, nausea, neutropenia, neuropathy, myopathy.
Non-nucleoside reverse transcriptase inhibitors (NNRTI)			Hepatotoxicity, rash.
Delavirdine	5.8 h (range 2–11)	Chronic	Hepatotoxicity, rash.
Efavirenz	3–5 h	Chronic	CNS effects: confusion, disengagement, dizziness, hallucinations, insomnia, somnolence, vivid dreams.
Nevirapine	45 h single dose; 25–30 h multiple doses	Chronic	Hepatotoxicity, rash.
Protease inhibitors (PIs)			Dyslipidemias, insulin resistance (diabetes mellitus), hepatotoxicity, lipodystrophy; osteoporosis.
Amprenavir	7.1–10.6 h	Chronic	Diarrhea, nausea, perioral/oral paresthesias, rash. Liquid product contains propylene glycol.
Indinavir	1.8 h	Chronic	Hyperbilirubinemia, kidney stones, nausea.
Lopinavir	5–6 h	Chronic	Diarrhea, nausea, increased cholesterol and triglycerides, and GGT. Solution contains 42.4% alcohol.
Nelfinavir	3–5 h	Chronic	Diarrhea, nausea, vomiting.
Ritonavir	2–4 h	Chronic	Diarrhea, nausea, vomiting, significant drug interactions.
Saquinavir	?	Chronic	Abdominal pain, diarrhea, nausea.

^aTenofovir is a *nucleotide* reverse transcriptase inhibitor (NtRTI).

II. Toxic dose

- A. **Acyclovir.** High-dose chronic therapy has caused crystalluria and renal failure. An acute ingestion of 20 g recovered. A 1.5-day-old and a 2-year-old child recovered from accidental overdoses involving 100 mg/kg 3 times a day for 4 days and 800 mg intravenously, respectively.
 - B. **Cidofovir.** Two adults received overdoses of 16.3 and 17.4 mg/kg, respectively, were treated with IV hydration and probenecid, and had no toxic effects.
 - C. **Efavirenz.** A 33-year-old female who ingested 54 g developed manic symptoms and recovered after 5 days.
 - D. **Foscarnet.** An adult receiving 12.5 g for 3 days developed seizures and died. Adults who received 1.14–8 times (average of 4 times) the recommended doses developed seizures and renal impairment.
 - E. **Ganciclovir.** All toxic reports have been after intravenous administration. The doses producing toxic effects after high chronic or inadvertent acute IV overdose have been variable. No toxic effects were noted in two adults who were given 3.5 g and 11 mg/kg for 7 doses over 3 days, respectively. However, single doses of 25 mg/kg and 6 g, or daily doses of 8 mg/kg for 4 days or 3 g for 2 days, resulted in neutropenia, granulocytopenia, pancytopenia, and/or thrombocytopenia. An adult and a 2-kg infant developed hepatitis after 10 mg/kg and 40-mg doses, respectively. An adult developed seizures after a 9-mg/kg dose, and others have had increased serum creatinine levels after 5- to 7-g doses.
 - F. **Indinavir.** Cases of acute and chronic overdoses, up to 23 times the recommended total daily dose of 2400 mg, resulting in interstitial nephritis, kidney stones, or acute renal dysfunction, have recovered after intravenous fluid therapy.
 - G. **Nevirapine.** An alleged 6-g ingestion in an adult was benign.
 - H. **Zidovudine.** Acute overdoses have been mild with ingestions of less than 25 g.
- III. **Clinical presentation.** Gastrointestinal symptoms are common after therapeutic doses and more remarkable after an acute overdose. Specific features of toxicity are described in Table II–12. **Lactic acidosis**, often severe and sometimes fatal, has been reported with antiretroviral drugs, particularly nucleoside reverse transcriptase inhibitors (NRTIs).
- IV. **Diagnosis** is usually based on the history of exposure. Unexplained mental status changes, neurologic deficits, weight gain, and renal abnormalities occurred after erroneous administration of acyclovir, particularly in pediatric patients.
- A. **Specific levels.** Serum levels are not commonly available for these agents and have not been particularly useful for predicting toxic effects.
 - B. **Other useful laboratory studies** include complete blood count (CBC), electrolytes, glucose, BUN, creatinine, liver function tests, and urinalysis. Lactic acid levels and arterial blood gases are recommended if lactic acidosis is suspected.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary.
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), or anaphylaxis (p 27) if they occur.
3. Replace fluid losses resulting from gastroenteritis with intravenous crystalloids.
4. Maintain steady urine flow with intravenous fluids to alleviate crystalluria and reverse renal dysfunction.
5. Treat lactic acidosis with judicious doses of sodium bicarbonate and by withdrawal of the offending drug.

B. **Specific drugs and antidotes.** There are no specific antidotes for these agents.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.

2. Hospital. Administer activated charcoal. Consider gastric lavage after massive or recent ingestion, although it may be ineffective in recovering much drug due to the large size of many of these pills.

D. Enhanced elimination. The few reported overdoses for these agents have been benign or associated with mild toxicities. Hemodialysis can remove 60% of the total body burden of acyclovir. The role for enhanced elimination, however, has yet to be evaluated or employed after acute overdoses.

Lactate elevation above 5 mmol/L requires rapid withdrawal of antiretroviral treatment.)

► ARSENIC

Michael J. Kosnett, MD, MPH

Arsenic compounds have been used for many years in industrial, commercial, and pharmaceutical products, but recently the nature and extent of their use in the United States has changed significantly. Most arsenic-containing wood preservatives will be discontinued by the end of 2003, and with the exception of arsenic-impregnated gels in ant bait, virtually all other licensed use of inorganic arsenicals as herbicides and pesticides has ended. A few organoarsenicals, such as methane arsonates and cacodylic acid, continue to be used as herbicides and defoliants, and phenylarsenic compounds are used as feed additives for poultry and swine. Inorganic arsenic is used in the production of nonferrous alloys, semiconductors, and certain types of glass. After a long absence, inorganic arsenic was reintroduced to the US pharmacopeia in 2000, when intravenous arsenic trioxide (Trisenox™) received FDA approval as a cancer chemotherapy agent. Inorganic arsenic is sometimes found in folk remedies and tonics, particularly from Asian sources. Artesian well water can be contaminated by inorganic arsenic from natural geologic deposits, and elevated levels of arsenic may be encountered in mine tailings and sediments, and coal fly ash. Arsine, a hydride gas of arsenic, is discussed on page 119.

I. Mechanism of toxicity. Arsenic compounds may be organic or inorganic and may contain arsenic in either a pentavalent (arsenate) or trivalent (arsenite) form. Once absorbed, arsenicals exert their toxic effects through multiple mechanisms, including inhibition of enzymatic reactions vital to cellular metabolism, induction of oxidative stress, and alteration in gene expression and cell signal transduction. Although arsenite and arsenate undergo in vivo biotransformation to less toxic pentavalent monomethyl and dimethyl forms, there is evidence that the process also forms more toxic trivalent methylated compounds.

A. Soluble arsenic compounds, which are well absorbed after ingestion or inhalation, pose the greatest risk for acute human intoxication.

B. Inorganic arsenic dusts (such as arsenic trioxide) may exert irritant effects on the skin and mucous membranes. Contact dermatitis has also been reported. Although the skin is a minor route of absorption for most arsenic compounds, systemic toxicity has resulted from industrial accidents involving percutaneous exposure to highly concentrated liquid formulations.

C. The chemical warfare agent **lewisite** (dichloro [2-chlorovinyl]arsine) is a volatile vesicant liquid that causes immediate severe irritation and necrosis to the eyes, skin, and airways (see also p 372).

D. Arsenate and arsenite are **known human carcinogens** by both ingestion and inhalation.

II. **Toxic dose.** The toxicity of arsenic compounds varies considerably based on valence state, chemical composition, and solubility. Humans are generally more sensitive than other animals to the acute and chronic effects of arsenicals.

A. **Inorganic arsenic compounds.** In general, trivalent arsenic (As^{+3}) is 2–10 times more acutely toxic than pentavalent arsenic (As^{+5}). However, overexposure to either form produces a similar pattern of effects, requiring the same clinical approach and management.

1. Acute ingestion of as little as 100–300 mg of a soluble trivalent arsenic compound (eg, sodium arsenite) could be fatal.
2. The lowest observed acute effect level (LOAEL) for acute human toxicity is approximately 0.05 mg/kg, a dose associated with gastrointestinal distress in some individuals.
3. Death attributable to malignant arrhythmias has been reported after days to weeks of cancer chemotherapy regimens administering 0.15 mg/kg/day of arsenic trioxide intravenously.
4. Repeated ingestion of approximately 0.04 mg/kg/day can result in gastrointestinal distress and hematologic effects after weeks to months, and peripheral neuropathy after 6 months to several years. Lower chronic exposures, approximately 0.01 mg/kg/day, can result in characteristic skin changes (initially spotted pigmentation, followed within years by palmar-plantar hyperkeratosis) after intervals of 5–15 years.
5. The US National Research Council (2001) recently estimated that chronic ingestion of drinking water containing arsenic at a concentration of 10 mcg/L could be associated with an excess lifetime cancer risk greater than 1 in 1000. The latency period for development of arsenic-induced cancer is probably a decade or longer.

B. **Organic arsenic.** In general, pentavalent organoarsenic compounds are less toxic than either trivalent organoarsenic compounds or inorganic arsenic compounds. Marine organisms may contain large quantities of arsenobetaine, an organic trimethylated compound, which is excreted unchanged in the urine and produces no known toxic effects.

III. Clinical presentation

A. **Acute exposure** most commonly occurs after accidental, suicidal, or deliberate poisoning by ingestion. A single, massive dose produces a constellation of multisystemic signs and symptoms that emerge over the course of hours to weeks.

1. **Gastrointestinal effects.** After a delay of minutes to hours, diffuse capillary damage results in hemorrhagic gastroenteritis. Nausea, vomiting, abdominal pain and watery diarrhea are common. Although prominent GI symptoms may subside within 24 to 48 hours, severe multisystemic effects may still ensue.
2. **Cardiovascular effects.** In severe cases, extensive tissue third spacing of fluids combined with fluid loss from gastroenteritis may lead to hypotension, tachycardia, shock, and death. Metabolic acidosis and rhabdomyolysis may be present. After a delay of 1–6 days, there may be a second phase of congestive cardiomyopathy, cardiogenic or noncardiogenic pulmonary edema, and isolated or recurrent cardiac arrhythmias. Prolongation of the QT interval may be associated with torsade de pointes ventricular arrhythmia.
3. **Neurological effects.** Mental status may be normal, or there may be lethargy, agitation, or delirium. Delirium or obtundation may be delayed by 2–6 days. Generalized seizures may occur, but are rare. Symmetric, sensorimotor axonal peripheral neuropathy may evolve 1–5 weeks following acute ingestion, beginning with painful, distal dysesthesias, particularly in the feet. Ascending weakness and paralysis may ensue, leading in severe cases to quadriplegia and neuromuscular respiratory failure.

4. Hematologic effects. Pancytopenia, particularly leukopenia and anemia, characteristically develops within 1–2 weeks after acute ingestion. A relative eosinophilia may be present, and there may be basophilic stippling of red blood cells.

5. Dermatologic effects. Findings that occasionally appear after a delay of 1–6 weeks include desquamation (particularly involving palms and soles), a diffuse maculopapular rash, periorbital edema, and herpes zoster or herpes simplex. Transverse white striae in the nails (Aldrich-Mees lines) may become apparent months after an acute intoxication.

B. Chronic intoxication is also associated with multisystemic effects, which may include fatigue and malaise, gastroenteritis, leukopenia and anemia (occasionally megaloblastic), sensory predominant peripheral neuropathy, hepatic transaminase elevation, noncirrhotic portal hypertension, and peripheral vascular insufficiency. Skin disorders and cancer may occur (see below), and a growing body of epidemiological evidence links chronic arsenic ingestion with an increased risk of hypertension, cardiovascular mortality, and diabetes mellitus.

1. Skin lesions, which emerge gradually over a period of 1–10 years, typically begin with a characteristic pattern of spotted (“raindrop”) pigmentation on the torso and extremities, followed after several years by the development of hyperkeratotic changes on the palms and soles. Skin lesions may occur after lower doses than those causing neuropathy or anemia. Arsenic-related skin cancer, which includes squamous cell carcinoma, Bowen’s disease, and basal cell carcinoma, is characteristically multicentric, and in non-sun-exposed areas.

2. Cancer. Chronic inhalation increases the risk of lung cancer. Chronic ingestion is an established cause of cancer of the lung, bladder, and skin.

IV. Diagnosis is usually based on a history of exposure combined with a typical pattern of multisystemic signs and symptoms. Suspect acute arsenic poisoning in a patient with abrupt onset of abdominal pain, nausea, vomiting, watery diarrhea, and hypotension, particularly when followed by an evolving pattern of delayed cardiac dysfunction, pancytopenia, and peripheral neuropathy. Metabolic acidosis and elevated CPK may occur early in the course of severe cases. Some arsenic compounds, particularly those of lower solubility, are radiopaque and may be visible on a plain abdominal x-ray.

A. Specific levels. In the first 2–3 days after acute symptomatic poisoning, total 24-hour urinary arsenic excretion is typically in excess of several thousand micrograms (spot urine greater than 1000 mcg/L), and depending on the severity of poisoning, may not return to background levels (less than 50 mcg in a 24-hour specimen, or less than 30 mcg/L in a spot urine) for several weeks. Spot urine analyses are usually sufficient for diagnostic purposes.

1. Ingestion of seafood, which may contain very large amounts of nontoxic organoarsenicals such as arsenobetaine and arsenosugars, can “falsely” elevate measurements of *total* urinary arsenic for up to 3 days. Speciation of urinary arsenic by a laboratory capable of reporting the concentration of inorganic arsenic and its primary human metabolites, monomethylarsinic acid (MMA) and dimethylarsinic acid (DMA), may sometimes be helpful: background urine concentration of the sum of urinary inorganic arsenic, MMA, and DMA is usually less than 20 mcg/L in the absence of recent seafood ingestion. It should be noted that although arsenobetaine is excreted unchanged in the urine, arsenosugars, abundant in bivalve mollusks and seaweed, are metabolized in part to DMA.

2. Blood levels are highly variable and are rarely of value in diagnosis or management in patients capable of producing urine. Although whole-blood arsenic, normally less than 5 mcg/L, may be elevated early in acute intoxication, it may decline rapidly to the normal range despite persistent elevated urinary arsenic excretion and continuing symptoms.

3. **Elevated concentrations of arsenic in nails or hair** (normally less than 1 ppm) may be detectable in certain segmental samples for months after urine levels normalize, but should be interpreted cautiously owing to the possibility of external contamination.

B. Other useful laboratory studies include CBC with differential and smear for basophilic stippling, electrolytes, glucose, BUN and creatinine, liver enzymes, CPK, urinalysis, ECG and ECG monitoring, and abdominal and chest x-rays.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7)
2. Treat coma (see p 19), shock (p 16), and arrhythmias (pp 13–15) if they occur. Because of the association of arsenic with prolonged QT intervals, avoid quinidine, procainamide, and other type Ia antiarrhythmic agents. Phenothiazines should not be given as antiemetics or antipsychotics because of their ability to prolong the QT interval and lower the seizure threshold.
3. Treat hypotension and fluid loss with aggressive use of intravenous crystalloid solutions, and vasopressor agents if needed, to support blood pressure and optimize urine output.
4. Prolonged inpatient support and observation are indicated for patients with significant acute intoxication, because cardiopulmonary and neurological complications may be delayed for several days. Continuous cardiac monitoring beyond 48 hours is warranted in patients with persistent symptoms or evidence of toxin-related cardiovascular disturbance, including electrocardiographic abnormalities, or any degree of congestive heart failure.

B. Specific drugs and antidotes. Treat seriously symptomatic patients with *chelating agents*, which have shown therapeutic benefit in animal models of acute arsenic intoxication when administered promptly (ie, minutes to hours) after exposure. Treatment should not be delayed during the several days often required to obtain specific laboratory confirmation.

1. **Unithiol** (2,3-dimercaptopropanesulfonic acid, DMPS, Dimaval; see p 506), a water-soluble analog of dimercaprol (BAL) that can be administered intravenously, has the most favorable pharmacological profile for treatment of acute arsenic intoxication. Although published experience is sparse, 3–5 mg/kg every 4 hours by slow intravenous infusion over 20 minutes is a suggested starting dose. In the United States, the drug is available through compounding pharmacists.
2. **Dimercaprol** (BAL, British anti-Lewisite, 2-3 dimercaptopropanol; see p 413) is the chelating agent of second choice if unithiol is not immediately available. The starting dose is 3–5 mg/kg by deep intramuscular injection every 4–6 hours. Lewisite burns to the skin and eyes can be treated with topical inunctions of dimercaprol.
3. Once patients are hemodynamically stable and gastrointestinal symptoms have subsided, parenteral chelation may be changed to oral chelation with either **oral unithiol**, or **oral succimer** (DMSA, 2-3 dimercaptosuccinic acid; see p 501). A suggested dose of unithiol is 4–8 mg/kg orally every 6 hours. Alternatively, give succimer 7.5 mg/kg orally every 6 hours, or 10 mg/kg orally every 8 hours.
4. The therapeutic endpoints of chelation are poorly defined. For chelation instituted to treat symptomatic acute intoxication, one empiric approach would be to continue treatment (initially parenterally, then orally) until total urinary arsenic levels are less than 500 mcg/24 hours (or spot urine < 300 mcg/L), levels below those associated with overt symptoms in acutely poisoned adults. Alternatively, oral chelation could be continued until total urinary arsenic levels reach background levels (< 50 mcg/24 hours, or spot urine < 30 mcg/L). The value of chelation for treatment of an established neuropathy (or prevention of an incipient neuropathy) has not been proved.

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal if available.

2. **Hospital.** Administer activated charcoal. However, note that animal and in vitro studies suggest that activated charcoal has a relatively poor affinity for inorganic arsenic salts. Consider gastric lavage for large ingestions.

D. Enhanced elimination. Hemodialysis may be of possible benefit in patients with concomitant renal failure, but otherwise contributes minimally to arsenic clearance. There is no known role for diuresis, hemoperfusion, or repeat-dose charcoal.

National Research Council: *Arsenic in Drinking Water: 2001 Update*. Washington, DC: National Academy Press, 2001 [<http://search.nap.edu/books/0309076293/html/>]. (Recent toxicology review and risk characterization for chronic arsenic exposure.)

Unnikrishnan D et al: Torsades de pointes in 3 patients with leukemia treated with arsenic trioxide. *Blood* 2001;97(5):1514–1516. [PMID: 11222403] (Torsade de pointes in 3 of 19 patients, after 42, 16, and 12 days of intravenous arsenic treatment; two cases were fatal.)

► ARSINE

Michael Kosnett, MD, MPH

Arsine is a colorless hydride gas (AsH_3) formed when arsenic comes in contact with hydrogen or with reducing agents in aqueous solution. Typically, exposure to arsine gas occurs in smelting operations or other industrial settings when arsenic-containing ores, alloys, or metallic objects come in contact with acidic (or occasionally alkaline) solutions, and newly formed arsine is liberated. Arsine is also used as a dopant in the microelectronics industry.

I. Mechanism of toxicity. Arsine is a potent hemolytic agent. Recent investigations suggest that hemolysis occurs when arsine interacts with heme to form a reactive intermediate that alters transmembrane ion flux and greatly increases intracellular calcium. **Note:** Arsenite and other oxidized forms of arsenic do **not** cause hemolysis. Deposition of massive amounts of hemoglobin in the renal tubule can cause acute renal injury. Massive hemolysis also decreases systemic oxygen delivery and creates hypoxic stress, and arsine and/or its reaction products exert direct cytotoxic effects on multiple organs.

II. Toxic dose. Arsine is the most toxic form of arsenic. Acute exposure guideline levels (AEGL) recently developed by the US EPA and the National Research Council indicate that disabling effects (AEGL-2) might occur after 30 minutes of exposure to ≥ 0.21 ppm, 1 hour of exposure to ≥ 0.17 ppm, or 8 hours of exposure to ≥ 0.02 ppm. Lethal or life-threatening effects (AEGL-3) might occur from 30 minutes of exposure to ≥ 0.63 ppm, 4 hours of exposure to ≥ 0.13 ppm, or 8 hours of exposure to ≥ 0.06 ppm. The level considered by NIOSH (1994) as “immediately dangerous to life or health” (IDLH) is 3 ppm. The odor threshold of 0.5–1.0 ppm provides insufficient warning properties.

III. Clinical presentation

A. Acute effects. Because arsine gas is not acutely irritating, inhalation causes **no immediate symptoms**. Those exposed to high concentrations may sometimes detect a garlic-like odor, but more typically they are unaware of the presence of a significant exposure. In most industrial accidents involving arsine, the hazardous exposure occurred over the course of 30 minutes to a few hours.

B. After a latent period of 2–24 hours (depending on the intensity of exposure), massive hemolysis occurs, along with early symptoms that may include malaise, headache, fever or chills, and numbness or coldness in the extremities. There may be concomitant gastrointestinal complaints of nausea, vomiting, and crampy pain in the abdomen, flank, or low back. In severe exposures, abrupt cardiovascular collapse and death may occur within 1 or 2 hours.

- C. **Hemoglobinuria** imparts a dark, reddish color to the urine, and the skin may develop a copper, bronze, or “jaundiced” discoloration possibly attributable to elevated plasma hemoglobin.
- D. Oliguria and **acute renal failure** often occur 1–3 days after exposure, and are a major aspect of arsine-related morbidity.
- E. A minority of patients may develop agitation and delirium within 1–2 days of presentation.
- F. **Chronic arsine poisoning**, a rarely reported condition, has been associated with headache, weakness, shortness of breath, nausea, vomiting, and anemia.

IV. Diagnosis. Arsine poisoning should be suspected in a patient who presents with the abrupt onset of hemolysis, hemoglobinuria, and progressive oliguria. A consistent work history or other likely source of exposure increases the index of suspicion, but is not always apparent.

A. Specific levels. Urine and whole-blood arsenic levels may be elevated, but are rarely available in time to assist with prompt diagnosis and management. Whole-blood arsenic concentrations in patients with severe arsine poisoning have ranged from several hundred to several thousand micrograms per liter.

B. Other useful laboratory studies

1. The complete blood count in the first few hours following acute exposure may be normal or reveal only moderate depression of the hematocrit or hemoglobin. However, within approximately 12–36 hours these values will progressively decline, with hemoglobin levels declining to 5–10 g/100 mL. The peripheral blood smear may reveal erythrocyte fragmentation and abnormal red blood cell forms, including characteristic “ghost cells” in which an enlarged membrane encloses a pale or vacant interior. Leukocytosis is common.
2. Initial urinalysis will typically be heme positive on dipstick, but with scant formed red blood cells on microscopic examination. Later, as oliguria progresses, an active urine sediment with red blood cells and casts will often emerge. Quantitative measurement of urine hemoglobin may rise to 3 g/L during significant hemolysis, and in some instances may exceed 10 g/L.
3. Serum bilirubin may show mild to moderate elevations (eg, 2–5 mg/dL) during the first 48 hours, with only a slight rise in liver transaminases.
4. Increases in BUN and serum creatinine will reflect acute renal insufficiency.

V. Treatment

A. Emergency and supportive measures

1. Provide vigorous intravenous hydration and, if needed, **osmotic diuresis with mannitol** (see p 464) to maintain urine output and reduce the risk of acute hemoglobinuric renal failure.
2. Clinical reports indicate that **prompt exchange transfusion with whole blood** is a key therapeutic intervention, and should be initiated for plasma or serum hemoglobin levels ≥ 1.5 g/dL, and/or signs of renal insufficiency or early acute tubular necrosis. Because of the time delay needed to obtain matched blood, the possible need for exchange transfusion in significantly exposed patients should be anticipated soon after they present.
3. Hemodialysis may be needed to treat progressive renal failure, but is not a substitute for exchange transfusion, which unlike hemodialysis removes arsenic-hemoprotein complexes thought to contribute to the ongoing hemolytic state.

B. Specific drugs and antidotes

1. The scant clinical experience with chelation in acute arsine poisoning is inconclusive, but limited animal and in vitro experimental studies suggest it is reasonable to initiate treatment with **dimercaprol** (BAL, British anti-Lewisite; see p 413), a relatively lipid-soluble chelator, in patients who present within 24 hours of exposure. The dose of dimercaprol during the

first 24 hours is 3–5 mg/kg every 4–6 hours by deep intramuscular injection.

2. After 24 hours, consider chelation with the water-soluble dimercapto chelating agents, oral or parenteral **unithiol** (DMPS; see p 506), or oral **succimer** (DMSA, Chemet™; p 501).
 3. Note that the recommendation to use dimercaprol rather than unithiol or succimer during the initial phases of poisoning is unique to arsine, and differs from the chelation recommendation for poisoning by other inorganic arsenicals, when initial use of unithiol is favored.
 4. Chelation is of uncertain efficacy, and should not substitute for nor delay the vigorous supportive measures outlined above.
- C. Decontamination.** Remove the victim from exposure. First responders should use self-contained breathing apparatus (SCBA) to protect themselves from any arsine remaining in the environment.
- D. Enhanced elimination.** As noted above, **prompt exchange transfusion with whole blood** is useful in patients with evidence of significant active hemolysis or evolving renal insufficiency. Whole donor blood may be infused through a central line at the same rate of blood removal through a peripheral vein, or techniques using modified hemodialysis circuits can be considered.

► ASBESTOS

John Balmes, MD

Asbestos is the name given to a group of naturally occurring silicates, chrysotile, amosite, and crocidolite, and the asbestiform types of tremolite, actinolite, and anthophyllite. Exposure to asbestos is a well-documented cause of pulmonary and pleural fibrosis, lung cancer, and mesothelioma, illnesses that may appear many years after exposure.

- I. **Mechanism of toxicity.** Inhalation of thin fibers longer than 5 microns produces lung fibrosis and cancer in animals (shorter fibers are generally phagocytosed by macrophages and cleared from the lungs). The exact mechanism of toxicity is unknown. Smoking cigarettes appears to enhance the likelihood of developing lung disease and malignancy.
- II. **Toxic dose.** A safe threshold of exposure to asbestos has not been established. Balancing potential health risks against feasibility of workplace control, the current OSHA federal asbestos standard sets a permissible exposure limit (PEL) of 0.1 fibers per cubic centimeter (fibers/cc) as an 8-hour time-weighted average. No worker should be exposed to concentrations in excess of 1 fiber/cc over a 30-minute period.
- III. **Clinical presentation.** After a latent period of 15–20 years, the patient may develop one or more of the following clinical syndromes:
 - A. **Asbestosis** is a slowly progressive fibrosing disease of the lungs. Pulmonary impairment resulting from lung restriction and decreased gas exchange is common.
 - B. **Pleural plaques** typically involve only the parietal pleura and are usually asymptomatic but provide a marker of asbestos exposure. Rarely, significant

lung restriction occurs as a result of severe pleural fibrosis involving both parietal and visceral surfaces.

C. Pleural effusions may occur as early as 5–10 years after the onset of exposure and are often not recognized as asbestos related.

D. Lung cancer is a common cause of death in patients with asbestos exposure, especially in cigarette smokers. **Mesothelioma** is a malignancy that may affect the pleura or the peritoneum. The incidence of **gastrointestinal cancer** may be increased in asbestos-exposed workers.

IV. Diagnosis is based on a history of exposure to asbestos (usually at least 15–20 years before onset of symptoms) and clinical presentation of one or more of the syndromes described above. Chest x-ray typically shows small, irregular, round opacities distributed primarily in the lower lung fields. Pleural plaques, diffuse thickening, or calcification may be present. Pulmonary function tests reveal decreased vital capacity and total lung capacity and impairment of carbon monoxide diffusion.

A. Specific tests. There are no specific blood or urine tests.

B. Other useful laboratory studies include chest x-ray, arterial blood gases, and pulmonary function tests.

V. Treatment

A. Emergency and supportive measures. Emphasis should be placed on **prevention** of exposure. All asbestos workers should be encouraged to stop smoking and to observe workplace control measures stringently.

B. Specific drugs and antidotes. There are none.

C. Decontamination

1. Inhalation. Persons exposed to asbestos dust and those assisting victims should wear protective equipment, including appropriate respirators and disposable gowns and caps. Watering down any dried material will help to prevent its dispersion into the air as dust.

2. Skin exposure. Asbestos is not absorbed through the skin. However, it may be inhaled from skin and clothes, so removal of clothes and washing the skin are recommended.

3. Ingestion. Asbestos is not known to be harmful by ingestion, so no decontamination is necessary.

D. Enhanced elimination. There is no role for these procedures.

Nelson HH, Kelsey KT: The molecular epidemiology of asbestos and tobacco in lung cancer. *Oncogene* 2002;21(48):7284–7288. [PMID: 12379872] (Review.)

► **AZIDE, SODIUM**

Jo Ellen Dyer, PharmD

Sodium azide is a highly toxic, white crystalline solid. It has come into widespread use in automobile airbags: its explosive decomposition to nitrogen gas provides rapid inflation of the airbag. In addition, sodium azide is used in the production of metallic azide explosives and as a preservative in laboratories. It has no current medical uses, but because of its potent vasodilatory effects, it has been evaluated as an antihypertensive agent.

I. Mechanism of toxicity

A. The mechanism of azide toxicity is unclear. Like cyanide and hydrogen sulfide, azide inhibits iron-containing respiratory enzymes such as cytochrome oxidase, resulting in cellular asphyxiation. Azide is also a potent, direct-acting vasodilator.

B. Although neutral solutions are stable, acidification rapidly converts the azide salt to **hydrazoic acid**, particularly in the presence of solid metals (eg, drain

pipes). Hydrazoic acid vapors are pungent and (at high concentrations) explosive. The acute toxicity of hydrazoic acid has been compared with that of hydrogen cyanide and hydrogen sulfide.

II. Toxic dose. Although several grams of azide are found in an automobile airbag, it is completely consumed and converted to nitrogen during the explosive inflation process, and toxicity has not been reported from exposure to spent airbags.

A. Inhalation. Irritation symptoms or pungent odor does not give adequate warning of toxicity. The recommended workplace ceiling limit (ACGIH TLV-C) is 0.29 mg/m³ for sodium azide and 0.11 ppm for hydrazoic acid. Air concentrations as low as 0.5 ppm may result in mucous membrane irritation, hypotension, and headache. A chemist who intentionally sniffed the vapor above a 1% hydrazoic acid solution became hypotensive, collapsed, and recovered 15 minutes later with residual headache. Workers in a lead azide plant exposed to air concentrations of 0.3–3.9 ppm experienced symptoms of headache, weakness, palpitations, mild smarting of the eyes and nose, and a drop in blood pressure. Laboratory workers adjacent to a sulfur analyzer emitting vapor concentrations of 0.5 ppm experienced symptoms of nasal stuffiness without detecting a pungent odor.

B. Dermal. Industrial workers handling bulk sodium azide experienced headache, nausea, faintness, and hypotension, but it is unclear whether the exposure occurred via dermal absorption or inhalation. An explosion of a metal waste drum containing a 1% sodium azide solution caused burns over a 45% body surface area and led to typical azide toxicity with a time course similar to oral ingestion; coma and hypotension developed within 1 hour followed by refractory metabolic acidosis, shock, and death 14 hours later.

C. Ingestion. Several serious or fatal poisonings occurred as a result of drinking large quantities of laboratory saline or distilled water containing 0.1–0.2% sodium azide as a preservative.

1. Ingestion of several grams can cause death within 1–2 hours.
2. Ingestion of 700 mg resulted in myocardial failure after 72 hours. Ingestion of 150 mg produced shortness of breath, tachycardia, restlessness, nausea, vomiting, and diarrhea within 15 minutes. Later, polydipsia, T wave changes on ECG, leukocytosis, and numbness occurred, lasting 10 days.
3. Doses of 0.65–3.9 mg/day given for up to 2.5 years have been used experimentally as an antihypertensive. The hypotensive effect occurred within 1 minute. Headache was the only complaint noted in these patients.

III. Clinical presentation

A. Irritation. Exposure to dust or gas may produce reddened conjunctivae and nasal and bronchial irritation that may progress to pulmonary edema.

B. Systemic toxicity. Both inhalation and ingestion are associated with a variety of dose-dependent systemic symptoms. Early in the course, hypotension and tachycardia occur that can evolve to bradycardia, ventricular fibrillation, and myocardial failure. Neurologic symptoms include headache, restlessness, facial flushing, loss of vision, faintness, weakness, hyporeflexia, seizures, coma, and respiratory failure. Nausea, vomiting, diarrhea, diaphoresis, and lactic acidosis also appear during the course.

IV. Diagnosis is based on the history of exposure and clinical presentation.

A. Specific levels. Specific blood or serum levels are not routinely available. A simple qualitative test can be used on powders and solid materials: azide forms a red precipitate in the presence of ferric chloride (use gloves and respiratory protection when handling the azide).

B. Other useful laboratory studies include electrolytes, glucose, arterial blood gases or pulse oximetry, and ECG.

V. Treatment. Caution: Cases involving severe azide ingestion are potentially dangerous to health-care providers. In the acidic environment of the stomach,

azide salts are converted to hydrazoic acid, which is highly volatile. Quickly isolate all vomitus or gastric washings, and keep the patient in a well-ventilated area. Wear appropriate respiratory protective gear if available; personnel should be trained to use it. Dispose of azide with care. Contact with heavy metals, including copper or lead found in water pipes, forms metal azides that may explode.

A. Emergency and supportive measures

1. Protect the airway and assist ventilation (see pp 1–7) if necessary. Insert an intravenous line and monitor the ECG and vital signs.
2. Treat coma (see p 19), hypotension (p 16), seizures (p 22), and arrhythmias (pp 10–15) if they occur.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen if available. Rescuers should wear self-contained breathing apparatus and appropriate chemical-protective clothing.
2. **Skin.** Remove and bag contaminated clothing and wash affected areas copiously with soap and water.
3. **Ingestion.** See caution statement above; isolate all vomitus or gastric washings to avoid exposure to volatile hydrazoic acid.
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of hypotension or seizures.
 - b. **Hospital.** Perform gastric lavage, and administer activated charcoal. The affinity of charcoal for azide is not known.

D. Enhanced elimination. There is no role for dialysis or hemoperfusion in acute azide poisoning.

Klein-Schwartz W et al: Three fatal sodium azide poisonings. *Med Toxicol Adverse Drug Exp* 1989;4(3):219–227. [PMID: 2818717] (Clinical course of 3 fatal cases ingesting 1.5 g to 2 tablespoons of azide, with lack of efficacy of nitrate therapy, and a review of the literature.)

► BARBITURATES

Timothy E. Albertson, MD, PhD

Barbiturates are used as hypnotic and sedative agents, for the induction of anesthesia, and for the treatment of epilepsy and status epilepticus. They are often divided into four major groups by their pharmacologic activity and clinical use: **ultrashort-acting, short-acting, intermediate-acting, and long-acting** (Table II–13). *Common combination products* containing barbiturates include Fiorinal™ (50 mg butalbital) and Donnatal™ (16 mg phenobarbital).

I. Mechanism of toxicity

- A. All barbiturates cause generalized **depression of neuronal activity** in the brain. Interaction with a barbiturate receptor leads to enhanced gamma-aminobutyric acid (GABA)-mediated chloride currents and results in synaptic inhibition. Hypotension that occurs with large doses is caused by depression of central sympathetic tone as well as by direct depression of cardiac contractility.
- B. **Pharmacokinetics** vary by agent and group (see Tables II–13 and II–59).
 1. **Ultrashort-acting** barbiturates are highly lipid soluble and rapidly penetrate the brain to induce anesthesia, then are quickly redistributed to other tissues. For this reason, the clinical duration of effect is much shorter than the elimination half-life for these compounds.
 2. **Long-acting barbiturates** are distributed more evenly and have long elimination half-lives, making them useful for once-daily treatment of epilepsy. Primidone (Mysoline) is metabolized to phenobarbital and phenylethyl-

TABLE II-13. COMMON BARBITURATES

Drug	Normal Terminal Elimination Half-Life (h)	Usual Duration of Effect (h)	Usual Hypnotic Dose (Adult) (mg)	Toxic Level (mg/L)
Ultrashort-acting				
Methohexital	3–5	< 0.5	50–120	>5
Thiopental	8–10	< 0.5	50–75	>5
Short-acting				
Pentobarbital	15–50	> 3–4	50–200	>10
Secobarbital	15–40	> 3–4	100–200	>10
Intermediate-acting				
Amobarbital	10–40	> 4–6	65–200	>10
Aprobarbital	14–34	> 4–6	40–160	>10
Butobarbital	35–50	> 4–6	100–200	>10
Butalbital	35		100–200	>7
Long-acting				
Mephobarbital	10–70	> 6–12	50–100	>30
Phenobarbital	80–120	> 6–12	100–320	>30

malonamide (PEMA); although phenobarbital accounts for only about 25% of the metabolites, it has the greatest anticonvulsant activity.

II. Toxic dose. The toxic dose of barbiturates varies widely and depends on the drug, the route and rate of administration, and individual patient tolerance. In general, toxicity is likely when the dose exceeds 5–10 times the hypnotic dose. Chronic users or abusers may have striking tolerance to depressant effects.

A. The potentially fatal **oral dose** of the shorter-acting agents is 2–3 g, compared with 6–10 g for phenobarbital.

B. Several deaths were reported in young women undergoing therapeutic abortion after they received rapid **intravenous injections** of as little as 1–3 mg/kg of methohexital.

III. Clinical presentation. The onset of symptoms depends on the drug and the route of administration.

A. Lethargy, slurred speech, nystagmus, and ataxia are common with mild to moderate intoxication. With higher doses, hypotension, coma, and respiratory arrest commonly occur. With deep coma, the pupils are usually small or mid-position; the patient may lose all reflex activity and appear to be dead.

B. Hypothermia is common in patients with deep coma, especially if the victim has suffered exposure to a cool environment. Hypotension and bradycardia commonly accompany hypothermia.

IV. Diagnosis is usually based on a history of ingestion and should be suspected in any epileptic patient with stupor or coma. Although skin bullae are sometimes seen with barbiturate overdose, these are not specific for barbiturates. Other causes of coma should also be considered (see p 19).

A. Specific levels of phenobarbital are usually readily available from hospital clinical laboratories; concentrations greater than 60–80 mg/L are usually associated with coma and those greater than 150–200 mg/L with severe hypotension. For short- and intermediate-acting barbiturates, coma is likely when the serum concentration exceeds 20–30 mg/L. Barbiturates are easily detected in routine urine toxicologic screening.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, arterial blood gases or pulse oximetry, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Protect the airway and assist ventilation (see pp 1–7) if necessary.
2. Treat coma (see p 19), hypothermia (p 20), and hypotension (p 16) if they occur.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for massive ingestion.

D. Enhanced elimination

1. **Alkalinization** of the urine (see p 55) increases the urinary elimination of phenobarbital but not other barbiturates. Its value in acute overdose is unproved, and it may potentially contribute to fluid overload and pulmonary edema.
2. **Repeat-dose activated charcoal** has been shown to decrease the half-life of phenobarbital, but it has not been shown to actually shorten the duration of coma.
3. **Hemoperfusion** or **hemodialysis** may be necessary for severely intoxicated patients not responding to supportive care (ie, with intractable hypotension).

Palmer BF: Effectiveness of hemodialysis in the extracorporeal therapy of phenobarbital overdose. *Am J Kidney Dis* 2000;36(3):640–643. [PMID: 10977799] (Use of a high-efficiency hemodialysis machine resulted in high clearance values and dramatic improvement after a life-threatening phenobarbital overdose.)

► BARIUM

Olga F. Woo, PharmD

Barium poisonings are uncommon and usually result from accidental contamination of food sources, suicidal ingestion, or occupational inhalation exposure. The water-soluble barium salts (acetate, carbonate, chloride, fluoride, hydroxide, nitrate, and sulfide) are highly toxic, whereas the insoluble salt, barium sulfate, is nontoxic because it is not absorbed. Soluble barium salts are found in depilatories, fireworks, ceramic glazes, and rodenticides and are used in the manufacture of glass and in dyeing textiles. Barium sulfide and polysulfide may also produce hydrogen sulfide toxicity (see p 224).

I. Mechanism of toxicity

- A. Systemic barium poisoning** is characterized by profound hypokalemia, leading to respiratory and cardiac arrest. The rapid onset of severe hypokalemia is most likely due to translocation of potassium into cells and blocked cellular potassium channel efflux. Barium ions have a direct action on muscle cell potassium permeability.
- B. Inhalation** of insoluble inorganic barium salts can cause baritosis, a benign pneumoconiosis. One death resulted from barium peroxide inhalation. Detonation of barium styphnate caused severe poisoning from inhalation and dermal absorption.
- C. Pharmacokinetics.** Barium is stored in bone and slowly excreted via the feces. Tissue distribution follows a three-compartment model with half-lives of 3.6, 34, and 1033 days.

- II. Toxic dose.** The minimum oral toxic dose of soluble barium salts is undetermined but may be as low as 200 mg. Lethal doses range from 1 to 30 g for various barium salts because absorption is influenced by gastric pH and foods high in sulfate. Patients have survived ingestions of 129 g and 421 g of barium sulfide.

- III. Clinical presentation.** Within minutes to a few hours after ingestion, victims develop profound hypokalemia and skeletal muscle weakness progressing to flaccid paralysis of the limbs and respiratory muscles. Ventricular arrhythmias, hypophosphatemia, rhabdomyolysis, acute renal failure, and coagulopathy may also occur. Gastroenteritis with severe watery diarrhea, mydriasis with impaired visual accommodation, and CNS depression are sometimes present. More often, patients remain conscious even when severely intoxicated.
- IV. Diagnosis** is based on a history of exposure, accompanied by rapidly progressive hypokalemia and muscle weakness.
- A. Specific levels.** Blood barium levels are not routinely available. One patient survived with a level of 3.7 mg/L, whereas postmortem levels in a fatal poisoning were less than 2 mg/L.
- B. Other useful laboratory studies** include electrolytes (potassium), BUN, creatinine, phosphorus, arterial blood gases or pulse oximetry, and continuous ECG monitoring. Measure serum potassium levels frequently.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat fluid losses from gastroenteritis with intravenous crystalloids.
 3. Attach a cardiac monitor and observe patient closely for at least 6–8 hours after ingestion.
- B. Specific drugs and antidotes.** Administer **potassium chloride** (see p 491) to treat symptomatic or severe hypokalemia. Large doses of potassium may be necessary (doses as high as 420 mEq over 24 hours have been given). Use potassium phosphate if the patient has hypophosphatemia.
- C. Decontamination** (see p 46)
1. **Prehospital.** Ipecac-induced vomiting may be useful for initial treatment at the scene (eg, children at home), but only if it can be given within a few minutes of exposure. Activated charcoal probably does not adsorb barium.
 2. **Hospital**
 - a. Perform gastric lavage. **Caution:** Rapidly progressive weakness may increase the risk of pulmonary aspiration.
 - b. **Magnesium sulfate or sodium sulfate** (30 g; children 250 mg/kg) should be administered orally to precipitate ingested barium as the insoluble sulfate salt.
 - c. Activated charcoal is not recommended unless there are co-ingestants.
- D. Enhanced elimination**
1. **Diuresis** with saline and furosemide to obtain a urine flow of 4–6 mL/kg/h may enhance barium elimination.
 2. Hemodialysis and hemoperfusion have not been evaluated in the treatment of serious barium poisoning. Hemodialysis might be helpful in correcting severe electrolyte disturbances.

Sigue G et al: From profound hypokalemia to life-threatening hyperkalemia: a case of barium sulfide poisoning. *Arch Intern Med* 2000;160(4):548–551. [PMID: 10695696] (A 25-year-old man developed hypokalemia [serum K 1.5 mEq/L], muscle weakness, respiratory arrest, and rhabdomyolysis after ingesting a depilatory containing barium sulfide. The potassium level rose to 8.3 mEq/L during treatment with oral and IV potassium.)

► BENZENE

Peter Wald, MD, MPH

Benzene, a clear volatile liquid with an acrid aromatic odor, is one of the most widely used industrial chemicals. It is a constituent by-product in gasoline; as a solvent for

fats, inks, paints, and plastics; and as a chemical intermediate in the synthesis of a variety of materials. It is generally not present in household products.

I. Mechanism of toxicity. Like other hydrocarbons, benzene can cause a chemical pneumonia if it is aspirated. See p 219 for a general discussion of hydrocarbon toxicity.

A. Once absorbed, benzene causes CNS depression and may sensitize the myocardium to the arrhythmogenic effects of catecholamines.

B. Benzene is also known for its chronic effects on the hematopoietic system, which are thought to be mediated by a reactive toxic intermediate metabolite.

C. Benzene is a known human carcinogen (ACGIH category A1).

II. Toxic dose. Benzene is rapidly absorbed by inhalation and ingestion and, to a limited extent, percutaneously.

A. The estimated lethal **oral** dose is 100 mL, but as little as 15 mL has caused death.

B. The recommended workplace limit (ACGIH TLV-TWA) for benzene **vapor** is 0.5 ppm (1.6 mg/m³) as an 8-hour time-weighted average. The short-term exposure limit (STEL) is 2.5 ppm. The level considered immediately dangerous to life or health (IDLH) is 500 ppm. A single exposure to 7500–20,000 ppm can be fatal. Chronic exposure to air concentrations well below the threshold for smell (2 ppm) is associated with hematopoietic toxicity.

C. The US Environmental Protection Agency (EPA) Maximum Contaminant Level (MCL) in water is 5 ppb.

III. Clinical presentation

A. Acute exposure may cause immediate CNS effects, including headache, nausea, dizziness, convulsions, and coma. Symptoms of CNS toxicity should be apparent immediately after inhalation or within 30–60 minutes after ingestion. Severe inhalation may result in noncardiogenic pulmonary edema. Ventricular arrhythmias may result from increased sensitivity of the myocardium to catecholamines. Benzene can cause chemical burns to the skin with prolonged or massive exposure.

B. After **chronic exposure**, hematologic disorders such as pancytopenia, aplastic anemia, acute myelogenous leukemia, and its variants may occur. Causality is suspected for chronic myelogenous leukemia, chronic lymphocytic leukemia, multiple myeloma, Hodgkin's disease, and paroxysmal nocturnal hemoglobinuria. There is unproven association between benzene exposure and acute lymphoblastic leukemia, myelofibrosis, and lymphomas. Chromosomal abnormalities have been reported, although no effects on fertility have been described in women after occupational exposure.

IV. Diagnosis of benzene poisoning is based on a history of exposure and typical clinical findings. With chronic hematologic toxicity, erythrocyte, leukocyte, and thrombocyte counts may first increase and then decrease before the onset of aplastic anemia.

A. Specific levels. Note: Smoke from one cigarette contains 60–80 mcg of benzene; a typical smoker inhales 1–2 mg of benzene daily. This may confound measurements of low-level benzene exposures.

1. Increased urine phenol levels may be useful indicators for monitoring workers' exposure (if diet is carefully controlled for phenol products). A spot urine phenol measurement higher than 50 mg/L suggests excessive occupational exposure. Urinary *trans*-muconic acid and S-phenylmercapturic acid (S-PMA) are more sensitive and specific tests for the measurement of low levels of benzene exposure, but are usually not readily available. S-PMA in urine is generally less than 15 mcg/g of creatinine.

2. Benzene can also be measured in expired air for up to 2 days after exposure.

3. Blood levels of benzene or metabolites are not clinically useful, except after an acute exposure. Normal levels are < 0.5 mcg/L.

B. Other useful laboratory studies include CBC, electrolytes, BUN, creatinine, liver function tests, ECG monitoring, and chest x-ray (if aspiration is suspected).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), arrhythmias (pp 13–15), and other complications if they occur.
3. Be cautious with use of any adrenergic agents (eg, epinephrine, metoprolol, albuterol) because of the possibility of myocardial sensitization.
4. Monitor vital signs and ECG for 12–24 hours after significant exposure.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Inhalation.** Immediately move the victim to fresh air and administer oxygen if available.
2. **Skin and eyes.** Remove clothing and wash the skin; irrigate exposed eyes with copious amounts of water or saline.
3. **Ingestion**
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of coma or convulsions.
 - b. **Hospital.** Administer activated charcoal. Consider gastric lavage for a recent (less than 30 minutes), large ingestion.

D. Enhanced elimination. Dialysis and hemoperfusion are not effective.

Barbera N et al: A fatal case of benzene poisoning. *J Forensic Sci* 1998;43(6):1250–1251. [PMID: 9846407] (The postmortem blood benzene level was 31.67 mg/L, and high concentrations were also found in the lungs, liver, kidneys, brain, and heart.)

► BENZODIAZEPINES

Ben Tsutaoka, PharmD

The drug class of benzodiazepines includes many compounds that vary widely in potency, duration of effect, presence or absence of active metabolites, and clinical use (Table II–14). Two nonbenzodiazepines, zolpidem and zaleplon, have similar effects and are included here. In general, death from benzodiazepine overdose is rare, unless the drugs are combined with other CNS-depressant agents such as ethanol or barbiturates. Newer potent, short-acting agents have been considered the sole cause of death in recent forensic cases.

I. Mechanism of toxicity. Benzodiazepines enhance the action of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). They also inhibit other neuronal systems by poorly defined mechanisms. The result is generalized depression of spinal reflexes and the reticular activating system. This can cause coma and respiratory arrest.

A. Respiratory arrest is more likely with newer short-acting benzodiazepines such as triazolam (Halcion™), alprazolam (Xanax™), and midazolam (Versed™). It has also been reported with zolpidem (Ambien™).

B. Cardiopulmonary arrest has occurred after rapid injection of diazepam, possibly because of CNS-depressant effects or because of the toxic effects of the diluent propylene glycol.

C. Pharmacokinetics. Most agents are highly protein bound (80–100%). Time to peak blood level, elimination half-lives, the presence or absence of active metabolites, and other pharmacokinetic values are given in Table II–59, p 381.

TABLE II-14. BENZODIAZEPINES

Drug	Half-Life (h)	Active Metabolite	Oral Adult Dose (mg)
Alprazolam	6.3–26.9	No	0.25–0.5
Chlordiazepoxide	40–120 ^a	Yes	5–50
Clonazepam	18–50	No	0.5–2
Clorazepate	40–120 ^a	Yes	3.75–30
Diazepam	40–120 ^a	Yes	5–20
Estazolam	8–28	No	1–2
Flunitrazepam	20	Yes	1–2
Flurazepam	47–100 ^a	Yes	15–30
Lorazepam	10–20	No	2–4
Midazolam	2.2–6.8	Yes	1–5 ^b
Oxazepam	5–20	No	15–30
Quazepam	70–75 ^a	Yes	7.5–15
Temazepam	3.5–18.4	No	15–30
Triazolam	1.5–5.5	No	0.125–0.5
Zaleplon ^c	1	No	5–20
Zolpidem	1.4–4.5	No	5–10

^aHalf-life of active metabolite, to which effects can be attributed.

^bIM or IV.

^cNot a benzodiazepine, but similar mechanism of action and clinical effects, which can be reversed with flumazenil.

II. Toxic dose. In general, the toxic:therapeutic ratio for benzodiazepines is very high. For example, oral overdoses of diazepam have been reported in excess of 15–20 times the therapeutic dose without serious depression of consciousness. On the other hand, respiratory arrest has been reported after ingestion of 5 mg of triazolam and after rapid intravenous injection of diazepam, midazolam, and many other benzodiazepines. Also, ingestion of another drug with CNS-depressant properties (eg, ethanol, barbiturates, opioids, etc) will likely produce additive effects.

III. Clinical presentation. Onset of CNS depression may be observed within 30–120 minutes of ingestion, depending on the compound. Lethargy, slurred speech, ataxia, coma, and respiratory arrest may occur. Generally, patients with benzodiazepine-induced coma have hyporeflexia and mid-position or small pupils. Hypothermia may occur. Serious complications are more likely when newer short-acting agents are involved or when other depressant drugs have been ingested.

IV. Diagnosis is usually based on the history of ingestion or recent injection. The differential diagnosis should include other sedative-hypnotic agents, antidepressants, antipsychotics, and narcotics. Coma and small pupils do not respond to naloxone but will reverse with administration of flumazenil (see below).

A. Specific levels. Serum drug levels are often available from commercial toxicology laboratories but are rarely of value in emergency management. Urine and blood qualitative screening may provide rapid confirmation of exposure. Certain immunoassays may not detect newer benzodiazepines or those in low concentrations. Triazolam and prazepam are rarely detectable.

B. Other useful laboratory studies include glucose, arterial blood gases, or pulse oximetry.

V. Treatment

A. Emergency and supportive measures

1. Protect the airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), hypotension (p 16), and hypothermia (p 20) if they occur. Hypotension usually responds promptly to supine position and intravenous fluids.

B. Specific drugs and antidotes. Flumazenil (see p 446) is a specific benzodiazepine receptor antagonist that can rapidly reverse coma. However, because benzodiazepine overdose by itself is rarely fatal, the role of flumazenil in routine management has yet to be established. It is administered intravenously with a starting dose of 0.1–0.2 mg, repeated as needed up to a maximum of 3 mg. It has some important potential drawbacks:

1. It may induce seizures in patients with tricyclic antidepressant overdose.
2. It may induce acute withdrawal, including seizures and autonomic instability, in patients who are addicted to benzodiazepines.
3. Resedation is common when the drug wears off after 1–2 hours, and repeated dosing or a continuous infusion is often required.

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal if available.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. There is no role for diuresis, dialysis, or hemoperfusion. Repeat-dose charcoal has not been studied.

Hamad A, Sharma N: Acute zolpidem overdose leading to coma and respiratory failure (Letter). *Intensive Care Med* 2001;27(7):1239. [PMID: 11534578] (Case report describing pure zolpidem overdose.)

► BETA-ADRENERGIC BLOCKERS

Neal L. Benowitz, MD

Beta-adrenergic blocking agents are widely used for the treatment of hypertension, arrhythmias, angina pectoris, migraine headaches, and glaucoma. Many patients with beta-blocker overdose will have underlying cardiovascular diseases or will be taking other cardioactive medications, both of which may aggravate beta-blocker overdose. A variety of beta blockers are available, with various pharmacologic effects and clinical uses (Table II–15).

I. Mechanism of toxicity. Excessive beta-adrenergic blockade is common to overdose with all drugs in this category. Although beta-receptor specificity is seen at low doses, it is lost in overdose.

A. Propranolol and other agents with membrane-depressant (quinidine-like) effects further depress myocardial contractility and conduction. Propranolol is also lipid soluble, which enhances brain penetration and can cause seizures and coma.

B. Pindolol and other agents with partial beta-agonist activity may cause tachycardia and hypertension.

C. Sotalol, which also has type III antiarrhythmic activity, prolongs the QT interval in a dose-dependent manner and may cause torsade de pointes (see p 14) and ventricular fibrillation.

D. Pharmacokinetics. Peak absorption occurs within 1–4 hours but may be much longer with sustained-release preparations. Volumes of distribution are generally large. Elimination of most agents is by hepatic metabolism, although nadolol is excreted unchanged in the urine and esmolol is rapidly inactivated by red blood cell esterases. (See also Table II–59, p 381.)

II. Toxic dose. The response to beta-blocker overdose is highly variable, depending on underlying medical disease or other medications. Susceptible patients

TABLE II-15. COMPARISON OF BETA-ADRENERGIC BLOCKING AGENTS

Drug	Usual Daily Adult Dose (mg/24 h)	Cardio-selective	Membrane Depression	Partial Agonist	Normal Half-Life (h)
Acebutolol	400–800	+	+	+	3–6
Alprenolol	200–800	0	+	++	2–3
Atenolol	50–100	+	0	0	4–10
Betaxolol ^a	10–20	+	0	0	12–22
Bisoprolol	5–20	+	0	0	8–12
Carteolol	2.5–10	0	0	+	6
Carvedilol ^c	6.25–50	0	0	0	6–10
Esmolol ^b		+	0	0	9 min
Labetalol ^c	200–800	0	+	0	6–8
Levobunolol ^a		0	0	0	5–6
Metoprolol	100–450	+	+/-	0	3–7
Nadolol	80–240	0	0	0	10–24
Oxyprenolol	40–480	0	+	++	1–3
Penbutolol	20–40	0	0	+	17–26
Pindolol	5–60	0	+	+++	3–4
Propranolol	40–360	0	++	0	2–6
Sotalol ^d	160–480	0	0	0	5–15
Timolol ^a	20–80	0	0	+/-	2–4

^aAlso available as ophthalmic preparation.

^bIntravenous infusion.

^cAlso has alpha-adrenergic blocking activity.

^dClass III antiarrhythmic activity.

may have severe or even fatal reactions to therapeutic doses. There are no clear guidelines, but ingestion of only 2–3 times the therapeutic dose (see Table II-15) should be considered potentially life-threatening in all patients. Atenolol and pindolol appear to be less toxic than other agents.

III. Clinical presentation. The pharmacokinetics of beta-blockers vary considerably, and duration of poisoning may range from minutes to days.

A. Cardiac disturbances, including hypotension and bradycardia, are the most common manifestations of poisoning. Atrioventricular block, intraventricular conduction disturbances, cardiogenic shock, and asystole may occur with severe overdose, especially with membrane-depressant drugs such as propranolol. The ECG usually shows a normal QRS duration with increased PR intervals; QRS widening occurs with massive intoxication.

B. CNS toxicity, including convulsions, coma, and respiratory arrest, is commonly seen with propranolol and other membrane-depressant and lipid-soluble drugs.

C. Bronchospasm is most common in patients with preexisting asthma or chronic bronchospastic disease.

D. Hypoglycemia and hyperkalemia may occur.

IV. Diagnosis is based on the history of ingestion, accompanied by bradycardia and hypotension. Other drugs that may cause a similar presentation after overdose include sympatholytic and antihypertensive drugs, digitalis, and calcium channel blockers.

A. Specific levels. Measurement of beta-blocker serum levels may confirm the diagnosis but does not contribute to emergency management. Metoprolol, labetalol, and propranolol may be detected in comprehensive urine toxicology screening.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, arterial blood gases, and 12-lead ECG and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), hyperkalemia (p 37), and hypoglycemia (p 34) if they occur.
3. Treat bradycardia with atropine, 0.01–0.03 mg/kg IV; isoproterenol (start with 4 mcg/min and increase infusion as needed); or cardiac pacing.
4. Treat bronchospasm with nebulized bronchodilators (see p 8).
5. Continuously monitor the vital signs and ECG for at least 6 hours after ingestion.

B. Specific drugs and antidotes

1. Bradycardia and hypotension resistant to the above measures should be treated with **glucagon**, 5–10 mg IV bolus, repeated as needed and followed by an infusion of 1–5 mg/h (see p 449). **Epinephrine** (intravenous infusion starting at 1–4 mcg/min and titrating to effect; see p 442) may also be useful.
2. Wide complex conduction defects caused by membrane-depressant poisoning may respond to **sodium bicarbonate**, 1–2 mEq/kg, as given for tricyclic antidepressant overdose (see p 419).
3. Torsade de pointes polymorphous ventricular tachycardia associated with QT prolongation resulting from sotalol poisoning can be treated with **isoproterenol** infusion, **magnesium**, or **overdrive pacing** (see p 14). Correction of hypokalemia may also be useful.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for large ingestions, especially involving propranolol. Gastric emptying is not necessary for small ingestions if activated charcoal can be given promptly.

D. Enhanced elimination. Most beta blockers, especially the more toxic drugs such as propranolol, are highly lipophilic and have a large volume of distribution (Vd). For those with a relatively small volume of distribution coupled with a long half-life or low intrinsic clearance (eg, acebutolol, atenolol, nadolol, or sotalol), hemoperfusion, hemodialysis, or repeat-dose charcoal may be effective.

Love JN: Acebutolol overdose resulting in fatalities. *J Emerg Med* 2000;18(3):341–344. [PMID: 10729673] (Two fatal cases demonstrated significant QTc prolongation and ventricular tachycardia in addition to other cardiotoxicity.)

Love JN, Elshami J: Cardiovascular depression resulting from atenolol intoxication. *Eur J Emerg Med* 2002;9(2):111–114. [PMID: 12131631] (A patient with massive atenolol ingestion developed hypotension in association with QRS prolongation; the authors point out that although rare, even hydrophilic agents can produce membrane-depressant effects that are more commonly seen with lipophilic drugs like propranolol.)

► BETA-2 ADRENERGIC STIMULANTS

Susan Kim, PharmD

Beta-adrenergic agonists can be broadly categorized as having beta-1 and beta-2 receptor activity. This section describes the toxicity of several beta-2-selective agonists that are commonly available for oral use: albuterol (salbutamol), metaproterenol, and terbutaline (Table II–16).

TABLE II-16. COMMONLY AVAILABLE BETA-2-SELECTIVE AGONISTS

Drug	Adult Dose (mg/d)	Pediatric Dose (mg/kg/d)	Duration (h)
Albuterol	8–16	0.3–0.8	4–8
Metaproterenol	60–80	0.9–2.0	4
Ritodrine ^a	40–120	N/A	4–6
Terbutaline	7.5–20	0.15–0.6	4–8

^aNo longer available as an oral formulation in the United States.

I. Mechanism of toxicity

A. Stimulation of beta-2 receptors results in relaxation of smooth muscles in the bronchi, uterus, and skeletal muscle vessels. At high toxic doses, selectivity for beta-2 receptors may be lost, and beta-1 effects may be seen.

B. Pharmacokinetics. Readily absorbed orally or by inhalation. Half-lives and other pharmacokinetic parameters are described in Table II-59 (p 381).

II. Toxic dose. Generally, a single ingestion of more than the total usual daily dose (see Table II-16) may be expected to produce signs and symptoms of toxicity. Pediatric ingestion of less than 1 mg/kg of albuterol is not likely to cause serious toxicity. Dangerously exaggerated responses to therapeutic doses of terbutaline have been reported in pregnant women, presumably as a result of pregnancy-induced hemodynamic changes.

III. Clinical presentation. Overdoses of these drugs affect primarily the cardiovascular system. Most overdoses, especially in children, result in only mild toxicity.

A. Vasodilation results in reduced peripheral vascular resistance and can lead to significant hypotension. The diastolic pressure is usually reduced to a greater extent than the systolic pressure, resulting in a wide pulse pressure and bounding pulse.

B. Tachycardia is a common reflex response to vasodilation and may also be caused by direct stimulation of beta-1 receptors as beta-2 selectivity is lost in high doses. Supraventricular tachycardia or ventricular extrasystoles are occasionally reported.

C. Agitation and skeletal muscle tremors are common. Seizures are rare.

D. Metabolic effects include hypokalemia, hyperglycemia, and lactic acidosis. Hypokalemia is caused by an intracellular shift of potassium rather than true depletion.

IV. Diagnosis is based on the history of ingestion. The findings of tachycardia, hypotension with a wide pulse pressure, tremor, and hypokalemia are strongly suggestive. Theophylline overdose (see p 354) may present with similar manifestations.

A. Specific levels are not generally available and do not contribute to emergency management. These drugs are not usually detectable on comprehensive urine toxicology screening.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, CPK (if excessive muscle activity suggests rhabdomyolysis), and ECG monitoring.

V. Treatment. Most overdoses are mild and do not require aggressive treatment.

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Monitor the vital signs and ECG for about 4–6 hours after ingestion.
3. If seizures or altered mental status occurs, they are most likely caused by cerebral hypoperfusion and should respond to treatment of hypotension (see below).
4. Treat hypotension initially with boluses of intravenous crystalloid, 10–30 mL/kg. If this fails to improve the blood pressure, use a beta-adrenergic blocker (see B, below).

5. Sinus tachycardia rarely requires treatment, especially in children, unless accompanied by hypotension or ventricular dysrhythmias. If treatment is necessary, use beta-adrenergic blockers (see B, below).
6. Hypokalemia does not usually require treatment, since it is transient and does not reflect a total body potassium deficit.
- B. Specific drugs and antidotes.** Hypotension, tachycardia, and ventricular arrhythmias are caused by excessive beta-adrenergic stimulation, and beta blockers are specific antagonists. Give **propranolol** (see p 496), 0.01–0.02 mg/kg IV, or **esmolol** (see p 443), 0.025–0.1 mg/kg/min IV. Use beta blockers cautiously in patients with a prior history of asthma or wheezing.
- C. Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal, if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. Enhanced elimination.** There is no role for these procedures.

Barnewolt BA et al: Metabolic effects of metaproterenol overdose: hypokalemia, hyperglycemia and hyperlactatemia. *Vet Hum Toxicol* 2001;43(3):158–160. [PMID: 11383657] (Case report illustrating metabolic effects associated with excessive beta-2 stimulation.)

► BORIC ACID, BORATES, AND BORON

Chi-Leung Lai, PharmD

Boric acid and sodium borate have been used for many years in a variety of products as antiseptics and fungistatic agents in baby talcum powder. Boric acid powder (99%) is still used as a pesticide against ants and cockroaches. In the past, repeated and indiscriminate application of boric acid to broken or abraded skin resulted in many cases of severe poisoning. Epidemics have also occurred after boric acid was mistakenly added to infant formula or used in food preparation. Although chronic toxicity seldom occurs now, acute ingestion by children at home is common.

Other boron-containing compounds with similar toxicity include boron oxide and orthoboric acid (sassolite).

I. Mechanism of toxicity

- A.** The mechanism of borate poisoning is unknown. Boric acid is not highly corrosive, but is irritating to mucous membranes. It probably acts as a general cellular poison. Organ systems most commonly affected are the skin, gastrointestinal tract, brain, liver, and kidneys.
- B. Pharmacokinetics.** The volume of distribution (Vd) is 0.17–0.50 L/kg. Elimination is mainly through the kidneys, and 85–100% of a dose may be found in the urine over 5–7 days. The elimination half-life is 12–27 hours.

II. Toxic dose

- A.** The **acute** single oral toxic dose is highly variable, but serious poisoning is reported to occur with 1–3 g in newborns, 5 g in infants, and 20 g in adults. A teaspoon of 99% boric acid contains 3–4 g. Most accidental ingestions in children result in minimal or no toxicity.
- B. Chronic** ingestion or application to abraded skin is much more serious than acute single ingestion. Serious toxicity and death occurred in infants ingesting 5–15 g in formula over several days; serum borate levels were 400–1600 mg/L.

III. Clinical presentation

- A.** After oral or dermal absorption, the earliest symptoms are gastrointestinal with vomiting and diarrhea. Vomiting and diarrhea may have a blue-green

color. Significant dehydration and renal failure can occur, with death caused by profound shock.

- B. Neurologic symptoms of hyperactivity, agitation, and seizures may occur early.
- C. An erythrodermic rash (boiled-lobster appearance) is followed by exfoliation after 2–5 days. Alopecia totalis has been reported.

IV. **Diagnosis** is based on a history of exposure, the presence of gastroenteritis (possibly with blue-green emesis), erythematous rash, acute renal failure, and elevated serum borate levels.

- A. **Specific levels.** Serum or blood borate levels are not generally available and may not correlate accurately with the level of intoxication. Analysis of serum for borates can be obtained from National Medical Services, Inc., telephone (215) 657-4900, or other large regional commercial laboratories. Normal serum or blood levels vary with diet, but are usually less than 7 mg/L. The serum boron level can be estimated by dividing the serum borate by 5.72.

- B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, and urinalysis.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and renal failure (p 39) if they occur.

- B. **Specific drugs and antidotes.** There is no specific antidote.

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal, if available.
2. **Hospital.** Administer activated charcoal (although boric acid is not well adsorbed). Consider gastric lavage for large ingestions.

- D. **Enhanced elimination. Hemodialysis** is effective and is indicated after massive ingestions and for supportive care of renal failure. Peritoneal dialysis has not proved effective in enhancing elimination in infants.

Teshima D et al: Usefulness of forced diuresis for acute boric acid poisoning in an adult. *J Clin Pharm Ther* 2001;26(5):387–390. [PMID: 11679030] (In this case report, 3.25 L of IV fluid and 100 mg of furosemide were given over 4 hours, and the measured urinary elimination of borate was reported to be equal to that reported with hemodialysis. The authors suggest that this procedure be considered in patients with massive boric acid ingestion.)

► BOTULISM

Ilene B. Anderson, PharmD

German physicians first identified botulism in the late 18th century when patients developed an often fatal disease after eating spoiled sausage. Four distinct clinical syndromes are now recognized: **food-borne botulism**, **infant botulism**, **wound botulism**, and adult intestinal colonization (or **adult-infant botulism**). Food-borne botulism, the most well-known form, results from ingestion of preformed toxin in improperly preserved home-canned vegetables, fish, or meats. In the last few decades, noncanned foods have also been reported to cause food-borne botulism. Examples include: fresh garlic in olive oil, sautéed onions, beef or turkey pot pie, baked potatoes, potato salad, smoked whitefish, turkey loaf, and turkey stuffing.

I. Mechanism of toxicity

- A. Botulism is caused by a heat-labile neurotoxin (botulin) produced by the bacteria *Clostridium botulinum*. Different strains of the bacterium produce seven distinct exotoxins: A, B, C, D, E, F, and G; types A, B, and E are most frequently involved in human disease. Botulin toxin irreversibly binds to cholinergic nerve terminals and prevents acetylcholine release from the axon. Severe muscle weakness results, and death is caused by respiratory failure. The toxin does not cross the blood-brain barrier.

- B.** Botulinum spores are ubiquitous in nature and, except for infants (and in rare situations, adults), the ingestion of spores is harmless. However, in an anaerobic environment with a pH of 4.6–7 the spores germinate and produce botulinum toxin. The spores are relatively heat stable but can be destroyed by pressure cooking at a temperature of at least 120°C (250°F) for 30 minutes. The toxin can be destroyed by boiling at 100°C (212°F) for 1 minute or heating at 80°C (176°F) for 20 minutes. Nitrites added to meats and canned foods inhibit clostridium growth.
- II. Toxic dose.** Botulin toxin is extremely potent; as little as one taste of botulin-contaminated food (approximately 0.05 mcg of toxin) may be fatal.
- III. Clinical presentation**
- A.** Classic **food-borne botulism** occurs after ingestion of preformed toxin in contaminated food. Initial symptoms are nonspecific and may include nausea, vomiting, sore throat, and abdominal discomfort. The onset of neurologic symptoms is typically delayed 12–36 hours but may vary from a few hours to as long as 8 days. The earlier the onset of symptoms, the more severe the illness. Diplopia, ptosis, sluggishly reactive pupils, dysarthria, dysphagia, dysphonia, and other cranial nerve weaknesses occur, followed by progressive symmetric descending paralysis. The patient's mentation remains clear, and there is no sensory loss. Pupils may be either dilated and unreactive or normal. Constipation and ileus due to decreased motility may occur. Profound weakness involving the respiratory muscles may cause respiratory failure and death.
- B.** **Infant botulism** is caused by ingestion of botulism spores (not preformed toxin) followed by in vivo production of toxin (typically type A or B) in the immature infant gut. Risk factors include age less than 1 year, breast-feeding, and ingestion of honey (which commonly contains botulism spores). The illness is characterized by hypotonia, constipation, tachycardia, difficulty in feeding, poor head control, and diminished gag, sucking, and swallowing reflexes. It is rarely fatal, and infants usually recover strength within 4–6 weeks.
- C.** **Wound botulism** occurs when the spores contaminate a wound, germinate in the anaerobic environment, and produce toxin in vivo that is then absorbed systemically, resulting in illness. It occurs most commonly in intravenous drug abusers who "skin pop" (inject the drug subcutaneously rather than intravenously), particularly those using "black tar" heroin. It has also been reported rarely with open fractures, dental abscesses, lacerations, puncture wounds, gunshot wounds, and sinusitis. Manifestations of botulism occur after an incubation period of 1–3 weeks.
- D.** **Adult intestinal colonization (or adult-infant) botulism** occurs rarely in adults after ingestion of botulism spores (not preformed toxin). As in infant botulism, spores germinate in the intestinal tract and the toxin is produced in vivo. Conditions predisposing patients to this rare form of botulism include a history of extensive gastrointestinal surgery, decreased gastric or bile acids, ileus, or prolonged antibiotic therapy resulting in altered gastrointestinal flora.
- IV. Diagnosis** is based on a high index of suspicion in any patient with a dry sore throat, clinical findings of descending cranial nerve palsies or gastroenteritis, and a history of ingestion of home-canned food. Symptoms may be slow in onset but are sometimes rapidly progressive. Electromyography may reveal normal conduction velocity but decreased motor action potential and no incremental response to repetitive stimulation. The differential diagnosis includes myasthenia gravis, Eaton-Lambert syndrome, and the Fisher variant of Guillain-Barré syndrome, as well as sudden infant death syndrome (SIDS), magnesium intoxication, paralytic shellfish poisoning, and tick-related paralysis (eg, *Dermacentor andersoni*).
- A. Specific levels.** Diagnosis is confirmed by determination of the toxin in serum, stool, or a wound; although these tests are useful for public health investigation, they cannot be used to determine initial treatment because the analysis takes more than 24 hours to perform. Obtain serum, stool, wound pus, vomitus, gastric contents, and suspect food for toxin analysis by the local or state health department. The results may be negative if the samples were collected late or the quantity of toxin is small.

- B. Other useful laboratory studies** include electrolytes, blood sugar, arterial blood gases, electromyogram, and cerebrospinal fluid (CSF) if CNS infection is suspected.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Obtain arterial blood gases and observe closely for respiratory weakness; respiratory arrest can occur abruptly.

B. Specific drugs and antidotes

1. Food-borne, wound, and adult intestinal colonization botulism

- a. **Botulin antitoxin** (see p 420) binds the circulating free toxin and prevents the progression of illness; however, it does not reverse established neurologic manifestations. It is most effective when given within 24 hours of the onset of symptoms.

(1) Contact the local or state health department or the Centers for Disease Control, Atlanta, GA; telephone (404) 639-2888 (24-hour number) to obtain antitoxin.

(2) Determine sensitivity to horse serum prior to treatment.

(3) The empiric dose for suspected botulism is one to two vials.

- b. **Guanidine** increases the release of acetylcholine at the nerve terminal, but has not been shown to be clinically effective.

- c. For **wound botulism**, antibiotic (penicillin) treatment is indicated, along with wound debridement and irrigation.

2. Infant botulism

- a. The horse serum-derived antitoxins are not recommended for infant botulism, but recent clinical trials demonstrated effectiveness of a **human tissue-derived botulism immune globulin (BIG)**; US Food and Drug Administration (FDA) approval is pending. To inquire about obtaining BIG, contact the Centers for Disease Control, Atlanta, GA; telephone (404) 639-2888. In California, contact the state Department of Health Services, telephone (510) 231-7600.

- b. Antibiotics are not recommended except for treatment of secondary infections. Cathartics are not recommended.

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal or induce vomiting if recent ingestion of known or suspected contaminated material has occurred.

2. **Hospital.** If recent ingestion is suspected, perform gastric lavage and administer activated charcoal.

- D. Enhanced elimination.** There is no role for enhanced elimination; the toxin binds rapidly to nerve endings, and any free toxin can be readily detoxified with antitoxin.

► BROMATES

Thomas R. Sands, PharmD

Bromate poisoning was most common during the 1940s and 1950s when it was a popular ingredient in home permanent neutralizers. Less toxic substances have been substituted for bromates in kits for home use, but poisonings still occur occasionally from professional products (bromate-containing permanent wave neutralizers have

been ingested in suicide attempts by professional hairdressers). Commercial bakeries often use bromate salts to improve bread texture, and bromates are components of fusing material for some explosives. Bromates were previously used in matchstick heads. Bromate-contaminated sugar was the cause of one reported epidemic of bromate poisoning.

I. Mechanism of toxicity. The mechanism is not known. The bromate ion is toxic to the cochlea, causing irreversible hearing loss, and nephrotoxic, causing acute tubular necrosis. Bromates may be converted to hydrobromic acid in the stomach, causing gastritis. Bromates are also strong oxidizing agents, capable of oxidizing hemoglobin to methemoglobin.

II. Toxic dose. The acute ingestion of 200–500 mg/kg of potassium bromate is likely to cause serious poisoning. Ingestion of 2–4 oz of 2% potassium bromate solution caused serious toxicity in children. The sodium salt is believed to be less toxic.

III. Clinical presentation

A. Within 2 hours of ingestion, victims develop gastrointestinal symptoms, including vomiting (occasionally with hematemesis), diarrhea, and epigastric pain. This may be accompanied by restlessness, lethargy, coma, and convulsions.

B. An asymptomatic phase of a few hours may follow before overt renal failure develops. Anuria is usually apparent within 1–2 days of ingestion; renal failure may be irreversible.

C. Tinnitus and irreversible sensorineural deafness occurs between 4 and 16 hours after ingestion in adults, but deafness may be delayed for several days in children.

D. Hemolysis and thrombocytopenia have been reported in some pediatric cases.

E. Methemoglobinemia (see p 261) has been reported, but is rare.

IV. Diagnosis is based on a history of ingestion, especially if accompanied by gastroenteritis, hearing loss, or renal failure.

A. Specific levels. Bromates may be reduced to bromide in the serum, but bromide levels do not correlate with the severity of poisoning. There are qualitative tests for bromates, but serum concentrations are not available.

B. Other useful laboratory studies include CBC, electrolytes, glucose, BUN, creatinine, urinalysis, audiometry, and methemoglobin.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19) and seizures (p 22) if they occur.
3. Replace fluid losses, treat electrolyte disturbances caused by vomiting and diarrhea, and monitor renal function. Perform hemodialysis as needed for support of renal failure.

B. Specific drugs and antidotes

1. **Sodium thiosulfate** (see p 505) may theoretically reduce bromate to the less toxic bromide ion. There are few data to support the use of thiosulfate, but in the recommended dose it is benign. Administer 10% thiosulfate solution, 10–50 mL (0.2–1 mL/kg) IV.
2. Treat methemoglobinemia with **methylen blue** (see p 466).

C. Decontamination (see p 46)

1. Prehospital

- a. Sodium bicarbonate (baking soda), 1 tsp in 8 oz of water PO, may prevent formation of hydrobromic acid in the stomach.
- b. Administer activated charcoal, if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ippecac to induce vomiting if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).

2. Hospital

- a. For large recent ingestions, consider gastric lavage with a 2% sodium bicarbonate solution to prevent formation of hydrobromic acid in the stomach.
- b. Administer activated charcoal.

- D. Enhanced elimination.** The bromate ion may be removed by hemodialysis, but this treatment has not been carefully evaluated. Since bromates are primarily excreted renally, initiating hemodialysis early in the course of a documented large ingestion may be prudent therapy to prevent irreversible hearing loss and renal failure.

Young YH et al: Toxic effects of potassium bromate and thioglycolate on vestibuloocular reflex systems of Guinea pigs and humans. *Toxicol Appl Pharmacol* 2001;177(2):103–111. [PMID: 11740909] (Chronic exposure to bromate and thioglycolates, found in hair-curling solutions, can lead to vertigo, tinnitus, or hearing loss.)

► BROMIDES

Delia A. Dempsey, MD

Bromide was once used as a sedative and an effective anticonvulsant, and until 1975 it was a major ingredient in various over-the-counter products such as Bromo-Seltzer™ and Dr. Miles' Nervine™. Bromism (chronic bromide intoxication) was once common, accounting for as many as 5–10% of admissions to psychiatric hospitals. Bromism is now rare, although bromides are occasionally used for treatment of epilepsy. Bromide is still found in photographic chemicals, as the bromide salt or other constituent of numerous medications, in some well water, bromide-containing hydrocarbons (eg, methyl bromide, ethylene dibromide, halothane), and in some soft drinks containing brominated vegetable oil. Foods fumigated with methyl bromide may contain some residual bromide, but the amounts are too small to cause toxicity.

I. Mechanism of toxicity

- A. Bromide ions substitute for chloride** in various membrane transport systems, particularly within the nervous system. It is preferentially reabsorbed over chloride by the kidney. Up to 30% of chloride may be replaced in the body. With high bromide levels, the membrane-depressant effect progressively impairs neuronal transmission.

- B. Pharmacokinetics.** The volume of distribution (V_d) of bromide is 0.35–0.48 L/kg. The half-life is 9–12 days, and bioaccumulation occurs with chronic exposure. Clearance is about 26 mL/kg/day and elimination is renal. Bromide is excreted in breast milk. It crosses the placenta, and neonatal bromism has been described.

- II. Toxic dose.** The adult therapeutic dose of bromide is 3–5 g. One death has been reported after ingestion of 100 g of sodium bromide. Chronic consumption of 0.5–1 g per day may cause bromism.

- III. Clinical presentation.** Death is rare. Acute oral overdose usually causes nausea and vomiting from gastric irritation. Chronic intoxication can result in a variety of neurologic, psychiatric, gastrointestinal, and dermatologic effects.

- A. Neurologic and psychiatric** manifestations are protean and include restlessness, irritability, ataxia, confusion, hallucinations, psychosis, weakness, stupor, and coma. At one time bromism was responsible for 5–10% of admissions to psychiatric facilities.

- B. Gastrointestinal** effects include nausea and vomiting (acute ingestion) and anorexia and constipation (chronic use).

- C. Dermatologic** effects include acneiform, pustular, or erythematous rashes. Up to 25% of patients are affected.

- IV. Diagnosis.** Consider bromism in any confused or psychotic patient with a high serum chloride level and a low or negative anion gap. The serum chloride level is often falsely elevated owing to interference by bromide in the analytic test; the degree of elevation varies with the instrument.

- A. Specific levels.** Endogenous serum bromide does not usually exceed 5 mg/L (0.06 mEq/L). The threshold for detection by usual methods is 50 mg/L. Ther-

apeutic levels are 50–100 mg/L (0.6–1.2 mEq/L); levels above 3000 mg/L (40 mEq/L) may be fatal.

- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, and abdominal x-ray (bromide is radiopaque).

V. Treatment

A. Emergency and supportive measures

1. Protect the airway and assist ventilation if needed (see pp 1–7).
2. Treat coma if it occurs (see p 19).

- B. Specific drugs and antidotes.** There is no specific antidote. However, administering chloride will promote bromide excretion (see below).

C. Decontamination (see p 47)

1. **Prehospital.** Activated charcoal is not effective. Ipecac-induced vomiting may be useful for initial treatment at the scene (eg, children at home) if it can be given within a few minutes of exposure.
2. **Hospital.** After recent ingestion, induce vomiting or perform gastric lavage, and administer a cathartic. Activated charcoal does not adsorb inorganic bromide ions, but it may adsorb organic bromides, and should also be used if other drug ingestion is suspected.

- D. Enhanced elimination.** Bromide is eliminated entirely by the kidney. The serum half-life can be dramatically reduced with fluids and chloride loading.

1. Administer **sodium chloride** intravenously as half-normal saline (D50/0.5 NS) at a rate sufficient to obtain a urine output of 4–6 mL/kg/h. **Furosemide**, 1 mg/kg, may assist urinary excretion.
2. **Hemodialysis** is effective and may be indicated in patients with renal insufficiency or severe toxicity. Hemoperfusion is not effective.

Horowitz BZ: Bromism from excessive cola consumption. *J Toxicol Clin Toxicol* 1997;35(3):315–320. [PMID: 9140329] (Chronic consumption of 2–4 L of cola containing brominated vegetable oil resulted in headache, fatigue, ataxia, and memory loss, with a measured serum Br level of 3180 mg/L. Hemodialysis was effective in reversing toxicity.)

► CADMIUM

Leslie M. Israel, DO

Cadmium (Cd) is found in sulfide ores, along with zinc and lead. Exposure is common during the mining and smelting of zinc, copper, and lead. The metallic form of Cd is used in electroplating because of its anticorrosive properties; the metallic salts are used as pigments and stabilizers in plastics; and Cd alloys are used in soldering and welding and in nickel-cadmium batteries. Cd solder in water pipes and Cd pigments in pottery can be sources of contamination of water and acidic foods.

- I. Mechanism of toxicity.** Inhaled Cd is at least 60 times more toxic than the ingested form. Fumes and dust may cause delayed chemical pneumonitis and resultant pulmonary edema and hemorrhage. Ingested Cd is a gastrointestinal tract irritant. Once absorbed, Cd is bound to metallothionein and filtered by the kidney, where renal tubule damage may occur.

II. Toxic dose

- A. Inhalation.** The ACGIH-recommended threshold limit value (TLV-TWA) for air exposure to Cd dusts and fumes is 0.01 (inhalable fraction) –0.002 (respirable dusts) mg/m³ as an 8-hour time-weighted average. Exposure to 5 mg/m³ inhaled for 8 hours may be lethal. The level considered immediately hazardous to life or health (IDLH) for Cd dusts or fumes is 9 mg Cd/m³.

- B. Ingestion.** Cd salts in solutions of greater than 15 mg/L may induce vomiting. The lethal oral dose ranges from 350 to 8900 mg.

III. Clinical presentation

- A. Direct contact** may cause local skin or eye irritation.

- B. Acute inhalation** may cause cough, wheezing, headache, fever, and, if severe, chemical pneumonitis and noncardiogenic pulmonary edema within 12–24 hours after exposure.
- C. Acute oral ingestion** of Cd salts causes nausea, vomiting, abdominal cramps, and diarrhea, sometimes bloody, within minutes after exposure. Deaths after oral ingestion result from shock or acute renal failure.
- D. Chronic** intake results in accumulation of Cd in bones, causing painful *itai-itai* (“ouch-ouch”) disease, and in kidneys, causing renal disease.
- IV. Diagnosis** is based on a history of exposure and the presence of respiratory complaints (after inhalation) or gastroenteritis (after ingestion).
 - A. Specific levels.** Whole-blood Cd levels may confirm the exposure; normal levels are less than 1 mcg/L. Very little Cd is excreted in the urine, until binding of Cd in the kidney is exceeded and renal damage occurs. Urine Cd values are normally less than 1 mcg/g of creatinine. Measures of tubular microproteinuria (beta-microglobulin, retinol-binding protein, albumin, and metallothionein) are used to monitor the early and toxic effects of Cd on the kidney.
 - B. Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, arterial blood gases or oximetry, and chest x-ray.
- V. Treatment**
 - A. Emergency and supportive measures**
 - 1. Inhalation.** Monitor arterial blood gases and obtain chest x-ray. Observe for at least 6–8 hours and treat wheezing and pulmonary edema (see pp 7–8) if they occur. After significant exposure, it may be necessary to observe for 1–2 days for delayed-onset noncardiogenic pulmonary edema.
 - 2. Ingestion.** Treat fluid loss caused by gastroenteritis with intravenous crystalloid fluids (see p 16).
 - B. Specific drugs and antidotes.** There is no evidence that chelation therapy (eg, with BAL, EDTA, or penicillamine) is effective, although various chelating agents have been used.
 - C. Decontamination**
 - 1. Inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
 - 2. Ingestion** (see p 47)
 - a. Prehospital.** Administer activated charcoal, if available (uncertain benefit). Do **not** induce vomiting because of the corrosive and irritant nature of Cd salts.
 - b. Hospital.** Perform gastric lavage. Administer activated charcoal, although the efficacy of charcoal is unknown. Do not give cathartics if the patient has diarrhea.
 - 3. Skin and eyes.** Remove contaminated clothing and wash exposed skin with water. Irrigate exposed eyes with copious amounts of tepid water or saline (see p 46).
 - D. Enhanced elimination.** There is no role for dialysis, hemoperfusion, or repeat-dose charcoal.

Pinot F et al: Cadmium in the environment: sources, mechanisms of biotoxicity, and biomarkers. *Rev Environ Health* 2000;15(3):299–323. [PMID: 11048333] (Review.)

► CAFFEINE

Christine A. Haller, MD

Caffeine is the most widely used psychoactive substance. Besides its well-known presence in coffee, tea, colas, and chocolate, it is available in many over-the-counter and prescription oral medications and as injectable caffeine sodium benzoate (occasionally used for neonatal apnea). Caffeine is widely used as an anorectant, a

coanalgesic, a diuretic, and a sleep suppressant. Botanical forms of caffeine, including yerba mate, guarana (*Paullinia cupana*), and kola nut (*Cola nitida*) are common constituents of “thermogenic” dietary supplements widely touted for weight loss and athletic enhancement (see also p 215). Although caffeine has a wide therapeutic index and rarely causes serious toxicity, there are many documented cases of accidental, suicidal, and iatrogenic intoxication, some resulting in death.

I. Mechanism of toxicity

A. Caffeine is a trimethylxanthine closely related to theophylline. It acts primarily through nonselective inhibition of adenosine receptors. In addition, with overdose there is considerable beta-1 and beta-2 adrenergic stimulation secondary to release of endogenous catecholamines.

B. Pharmacokinetics. Caffeine is rapidly and completely absorbed orally with a volume of distribution of 0.7–0.8 L/kg. Its elimination half-life is approximately 4–6 hours but can range from 3 hours in healthy smokers to 10 hours in non-smokers; after overdose the half-life may be as long as 15 hours. In infants less than 2–3 months old, metabolism is extremely slow and the half-life may exceed 24 hours. (See also Table II–59.) Caffeine is metabolized in the liver by cytochrome P-450, primarily the CYP1A2 isoenzyme, and is subject to several potential drug interactions, including inhibition by estrogens, cimetidine, norfloxacin, and alcohol. Tobacco (and marijuana) smoking accelerates caffeine metabolism.

II. Toxic dose. The reported lethal oral dose is 10 g (150–200 mg/kg), although one case report documents survival after a 24-g ingestion. In children, ingestion of 35 mg/kg may lead to moderate toxicity. Coffee contains 50–200 mg (tea, 40–100 mg) of caffeine per cup depending on how it is brewed. No-Doz and other sleep suppressants usually contain about 200 mg each. “Thermogenic” dietary supplements, sold as energy beverages, bars, capsules, tablets, or liquid drops, contain the equivalent of 40–200 mg of caffeine per serving in the form of concentrated plant extracts. As with theophylline, chronic administration of excessive doses may cause serious toxicity with relatively low serum concentrations compared with an acute single ingestion.

III. Clinical presentation

A. The earliest symptoms of **acute** caffeine poisoning are usually anorexia, tremor, and restlessness. These are followed by nausea, vomiting, tachycardia, and confusion. With serious intoxication, delirium, seizures, supraventricular and ventricular tachyarrhythmias, hypokalemia, and hyperglycemia may occur. Hypotension is caused by excessive beta-2–mediated vasodilation and is characterized by a low diastolic pressure and a wide pulse pressure.

B. Chronic high-dose caffeine intake can lead to “caffeinism” (nervousness, irritability, anxiety, tremulousness, muscle twitching, insomnia, palpitations, and hyperreflexia).

IV. Diagnosis is suggested by the history of caffeine exposure or the constellation of nausea, vomiting, tremor, tachycardia, seizures, and hypokalemia (also consider theophylline; see p 354).

A. Specific levels. Serum caffeine levels are not routinely available in hospital laboratories but can be determined at commercial toxicology laboratories. Toxic concentrations may be detected by cross-reaction with theophylline assays (see Table I–33, p 44). Coffee drinkers have caffeine levels of 1–10 mg/L, while levels of 80 mg/L have been associated with death. The level associated with a high likelihood of seizures is unknown.

B. Other useful laboratory studies include electrolytes, glucose, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat seizures (see p 22) and hypotension (p 16) if they occur. Extreme anxiety or agitation may respond to benzodiazepines such as IV lorazepam (p 415).

3. Hypokalemia usually resolves without aggressive treatment.
4. Monitor ECG and vital signs for at least 6 hours after ingestion or until the serum level is documented to be decreasing.
- B. Specific drugs and antidotes.** Beta blockers effectively reverse cardiotoxic effects mediated by excessive beta-adrenergic stimulation. Treat tachyarrhythmias or hypotension with intravenous **propranolol**, 0.01–0.02 mg/kg (see p 496), or **esmolol**, 0.025–0.1 mg/kg/min (p 443), beginning with low doses and titrating to effect. Because of its short half-life and cardioselectivity, esmolol is preferred.
- C. Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal if available.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly, although gastric lavage should be considered for massive ingestion.
- D. Enhanced elimination.** Repeat-dose activated charcoal (see p 57) may enhance caffeine elimination. Seriously intoxicated patients (with multiple seizures, significant tachyarrhythmias, or intractable hypotension) may require hemodialysis or charcoal hemoperfusion (see p 55).

Haller CA et al: Pharmacology of ephedra alkaloids and caffeine after single-dose dietary supplement use. *Clin Pharmacol Ther* 2002;71(6):421–432. [PMID: 12087345] (Botanical stimulants can produce significant cardiovascular responses after a single dose.)

► CALCIUM ANTAGONISTS

Neal L. Benowitz, MD

Calcium antagonists (also known as calcium channel blockers or calcium blockers) are widely used to treat angina pectoris, coronary spasm, hypertension, hypertrophic cardiomyopathy, supraventricular cardiac arrhythmias, and migraine headache. Toxicity from calcium antagonists may occur with therapeutic use (often owing to drug interactions) or as a result of accidental or intentional overdose. Overdoses of calcium antagonists are frequently life threatening and represent an important source of drug-induced mortality.

- I. Mechanism of toxicity.** Calcium antagonists slow the influx of calcium through cellular calcium channels. Currently marketed agents act primarily on vascular smooth muscle and the heart. They result in coronary and peripheral vasodilation, reduced cardiac contractility, slowed (AV) nodal conduction, and depressed sinus node activity. Lowering of blood pressure through a fall in peripheral vascular resistance may be offset by reflex tachycardia, although this reflex response may be blunted by depressant effects on contractility and sinus node activity. Table II–17 summarizes usual doses, sites of activity, and half-lives of common calcium antagonists.
- A.** In usual therapeutic doses, amlodipine, felodipine, isradipine, nifedipine, and nitrendipine act primarily on blood vessels, whereas verapamil, diltiazem, and mibefradil act on both the heart and blood vessels. In overdose, however, this selectivity may be lost.
- B.** Bepridil, used primarily for refractory angina pectoris, has verapamil-like effects on the heart, inhibits the fast sodium channel, and has type III antiarrhythmic activity. Bepridil also has proarrhythmic effects, especially in the presence of hypokalemia.
- C.** Nimodipine has a greater action on cerebral arteries and is used to reduce vasospasm after recent subarachnoid hemorrhage.
- D.** Important **drug interactions** may result in toxicity. Hypotension is more likely to occur in patients taking beta blockers, nitrates, or both, especially if they are hypovolemic after diuretic therapy. Patients taking disopyramide or other

TABLE II-17. COMMON CALCIUM ANTAGONISTS

Drug	Usual Adult Daily Dose (mg)	Elimination Half-Life (h)	Primary Site(s) of activity ^a
Amlodipine	2.5–10	30–50	V
Bepidil	200–400	24	M,V
Diltiazem	90–360 (PO) 0.25 mg/kg (IV)	4–6	M,V
Felodipine	5–30	11–16	V
Isradipine	5–25	8	V
Mibefradil ^c	50–100	17–25	M ^b , V
Nicardipine	60–120	8	V
Nifedipine	30–120	2–5	V
Nisoldipine	20–40	4	V
Nitrendipine	40–80	2–20	V
Verapamil	120–480 (PO) 0.075–0.15 mg/kg (IV)	2–8	M,V

^aMajor toxicity: M = myocardial (decreased contractility, AV block); V = vascular (vasodilation).

^bMyocardial effect limited to bradycardia and AV block.

^cMibefradil has been removed from the US market.

depressant cardioactive drugs and those with severe underlying myocardial disease are also at risk for hypotension. Life-threatening bradyarrhythmias, including asystole, may occur when beta blockers and verapamil are given together parenterally. Propranolol also inhibits the metabolism of verapamil.

E. Pharmacokinetics. Absorption may be delayed with sustained-release preparations. Most agents are highly protein bound and have large volumes of distribution (Vd). Eliminated mainly via extensive hepatic metabolism. In a report on two patients with verapamil overdoses (serum levels 2200 and 2700 ng/mL), the elimination half-lives were 7.8 and 15.2 hours. (See also Table II-59, p 381.)

II. Toxic dose. Usual therapeutic daily doses for each agent are listed in Table II-17. The toxic:therapeutic ratio is relatively small, and serious toxicity may occur with therapeutic doses. For example, severe bradycardia can occur with therapeutic doses of mibefradil. Any dose greater than the usual therapeutic range should be considered potentially life threatening. Note that many of the common agents are available in sustained-release formulations, which can result in delayed onset or sustained toxicity.

III. Clinical presentation

A. The primary features of calcium antagonist intoxication are **hypotension** and **bradycardia**.

1. Hypotension may be caused by peripheral vasodilation, reduced cardiac contractility, slowed heart rate, or a combination of all of these.
2. Bradycardia may result from sinus bradycardia, second- or third-degree AV block, or sinus arrest with junctional rhythm.
3. Most calcium antagonists do not affect intraventricular conduction, so the QRS duration is usually unaffected. The PR interval may be prolonged even with therapeutic doses of verapamil. Bepidil prolongs the QT interval and may cause ventricular arrhythmias, including torsade de pointes (see p 14). Mibefradil also causes QT prolongation, and has been associated with ventricular arrhythmias. It has been removed from the US market.

B. Noncardiac manifestations of intoxication include nausea and vomiting, abnormal mental status (stupor and confusion), metabolic acidosis (probably re-

sulting from hypotension), and hyperglycemia (owing to blockade of insulin release).

IV. Diagnosis. The findings of hypotension and bradycardia, particularly with sinus arrest or AV block, in the absence of QRS interval prolongation should suggest calcium antagonist intoxication. The differential diagnosis should include beta blockers and other sympatholytic drugs.

A. Specific levels. Serum or blood drug levels are not widely available. Diltiazem and verapamil may be detectable in comprehensive urine toxicology screening.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, arterial blood gases or oximetry, and ECG and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), hypotension (p 16), and bradyarrhythmias (p 10) if they occur. The use of cardiopulmonary bypass to allow time for liver metabolism has been reported in a patient with massive verapamil poisoning. Cardiac pacing should be considered for bradyarrhythmias that are contributing to hypotension.
3. Monitor the vital signs and ECG for at least 6 hours after alleged ingestion. Admit symptomatic patients for at least 24 hours.

B. Specific drugs and antidotes

1. **Calcium** (see p 424) usually promptly reverses the depression of cardiac contractility, but it does not affect sinus node depression or peripheral vasodilation and has variable effects on AV nodal conduction. Administer **calcium chloride** 10%, 10 mL (0.1–0.2 mL/kg) IV, or **calcium gluconate** 10%, 20 mL (0.3–0.4 mL/kg) IV. Repeat every 5–10 minutes as needed. In case reports, doses as high as 10–15 g over 1–2 hours and 30 g over 12 hours have been administered without apparent calcium toxicity.
2. **Glucagon** (see p 449), **epinephrine** (see p 442), and **inamrinone** (see p 454) have been reported to increase blood pressure in patients with refractory hypotension. Glucagon and epinephrine can also increase the heart rate.
3. **Hyperinsulinemia/euglycemia** (HIE) therapy is effective in animal models of severe intoxication and has been reportedly beneficial in several human case reports. The putative mechanism is correction of calcium antagonist-induced hypoinsulinemia, leading to improved cell carbohydrate metabolism, increased myocardial contractility and peripheral vascular resistance, and correction of acidosis. The treatment is not expected to improve conduction block or bradycardia. A bolus of **insulin** 0.5–1 U/kg (see p 455) is followed by an infusion of 0.5–1 U/kg/h, and is accompanied by an initial bolus of **glucose** (25 g or 50 mL of D₅₀W; children 0.5 g/kg as D₂₅W) followed by additional boluses and infusions to maintain the serum glucose between 100 and 200 mg/dL. Blood sugar levels should be checked every 15–20 minutes, and serum potassium must be followed and corrected as needed.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for all but the most trivial ingestions. For large ingestions of a sustained-release preparation, consider whole-bowel irrigation (see p 52) in addition to repeated doses of charcoal (see p 57). Continue charcoal administration for up to 48–72 hours.

D. Enhanced elimination. Owing to extensive protein binding, dialysis and hemoperfusion are not effective. Repeat-dose activated charcoal has not been evaluated, but may serve as an adjunct to gastrointestinal decontamination after overdose with sustained-release preparations.

Boyer EW et al: Hyperinsulinemia/euglycemia therapy for calcium channel blocker poisoning. *Pediatr Emerg Care* 2002;18(1):36–37. [PMID: 11862138] (Brief report.)

Ilsbister GK: Delayed asystolic cardiac arrest after diltiazem overdose; resuscitation with high dose intravenous calcium. *Emerg Med J* 2002;19(4):355–357. [PMID: 12101159] (Case report of 1.8- to 3.6-g diltiazem ingestion with severe cardiotoxicity, which responded to 13.5 g calcium as well as epinephrine.)

► CAMPHOR AND OTHER ESSENTIAL OILS

Ilene B. Anderson, PharmD

Camphor is one of several essential oils (volatile oils) derived from natural plant products that have been used for centuries as topical rubefaciants and counterirritant agents for analgesic and antipruritic purposes (Table II–18). Camphor and other essential oils are found in many over-the-counter remedies such as BenGay Ultra-Strength™ (4% camphor, 10% menthol, 30% methyl salicylate), Campho-Phenique™ (10.8% camphor, 4.66% phenol), Vicks Vaporub™ (4.73% camphor, 2.6% menthol, 1.2% eucalyptus oil, 4.5% turpentine spirits), camphorated oil (20% camphor), and Mentholatum™ (9% camphor, 1.35% menthol, 1.96% eucalyptus oil, 1.4% turpentine spirits). Toxic effects have occurred primarily when camphorated oil was mistakenly administered instead of castor oil, and in accidental pediatric ingestions.

TABLE II–18. SOME ESSENTIAL OILS

Name	Comments
Birch oil	Contains 98% methyl salicylate (equivalent to 1.4 g aspirin per mL; see salicylates, p 331)
Camphor	Pediatric toxic dose 1 g (see text).
Cinnamon oil	Stomatitis and skin burns can result from prolonged contact. Potent antigen. Smoked as a hallucinogen.
Clove oil	Contains 80–90% eugenol. Anion gap acidosis and CNS depression after acute ingestion. Clove cigarettes may cause irritant tracheobronchitis, hemoptysis.
Eucalyptus oil	Contains 70% eucalyptol. Toxic dose is 5 mL; may cause rapid CNS depression.
Eugenol	A phenol derived from clove oil. Coma, seizures, metabolic acidosis, coagulopathy, and liver damage can occur after ingestion by children.
Guaiacol	Nontoxic.
Lavender oil	Used in doses of 0.1 mL as a carminative. Contains trace amounts of coumarin (see p 378). May cause photosensitization.
Menthol	An alcohol derived from various mint oils. Toxic dose is 2 g.
Myristica oil	Nutmeg oil. A carminative in a dose of 0.03 mL. Used as a hallucinogen (2–4 tbsps of ground nutmeg can cause psychogenic effects).
Pennyroyal oil	Moderate to severe toxicity with ingestion of more than 10 mL. Fatal coma and hepatic necrosis occurred after ingestion of 30 mL by an 18-year-old woman. <i>N</i> -acetylcysteine may be effective in preventing hepatic necrosis.
Peppermint oil	Contains 50% menthol. Toxic dose is 5–10 g.
Thymol	Used as an antiseptic (see phenol, p 302). May cause allergic contact dermatitis.
Turpentine oils	Toxic dose 15 mL in children; 140 mL in adults may be fatal. Can cause pneumonitis if aspirated.
Wintergreen oil	Contains methyl salicylate 98% (equivalent to 1.4 g of aspirin per mL; see Salicylates, p 331).

- I. Mechanism of toxicity.** After topical application, essential oils produce dermal hyperemia followed by a feeling of comfort, but if ingested they can cause systemic toxicity. Most essential oils cause CNS stimulation or depression. **Camphor** is a CNS stimulant that causes seizures shortly after ingestion. The underlying mechanism is unknown. Camphor is rapidly absorbed from the gastrointestinal tract and is metabolized by the liver. It is not known whether metabolites contribute to toxicity.
- II. Toxic dose.** Serious poisonings and death have occurred in children after ingestion of as little as 1 g of camphor. This is equivalent to just 10 mL of Camphor-Phenique or 5 mL of camphorated oil. Recovery after ingestion of 42 g in an adult has been reported. The concentrations of other essential oils range from 1 to 20%; doses of 5–15 mL are considered potentially toxic.
- III. Clinical presentation** (see also Table II-18)
- A. Oral.** Manifestations of **acute** oral overdose usually occur within 5–30 minutes after ingestion. Burning in the mouth and throat occurs immediately, followed by nausea and vomiting. Ataxia, drowsiness, confusion, restlessness, delirium, muscle twitching, and coma may occur. Camphor typically causes abrupt onset of seizures about 20–30 minutes after ingestion. Death may result from CNS depression and respiratory arrest or may be secondary to status epilepticus. **Chronic** camphor intoxication may produce symptoms similar to Reye's syndrome.
- B.** Prolonged **skin contact** may result in a burn.
- C. Smoking** (eg, clove cigarettes) or inhaling essential oils may cause tracheobronchitis.
- IV. Diagnosis** is usually based on a history of exposure. The pungent odor of camphor and other volatile oils is usually apparent.
- A. Specific levels** are not available.
- B. Other useful laboratory studies** include electrolytes, glucose, liver transaminases, and arterial blood gases (if the patient is comatose or in status epilepticus).
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat seizures (see p 22) and coma (p 16) if they occur.
- B. Specific drugs and antidotes.** There are no specific antidotes for camphor. **N-acetylcysteine** (see p 405) may be effective for preventing hepatic injury after pennyroyal oil ingestion.
- C. Decontamination** (see p 46)
1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary for small ingestions if activated charcoal can be given promptly.
- D. Enhanced elimination.** The volumes of distribution of camphor and other essential oils are extremely large, and it is unlikely that any enhanced removal procedure will remove significant amounts of camphor. Poorly substantiated case reports have recommended hemoperfusion.

Emery DP, Corban JG: Camphor toxicity. *J Paediatr Child Health* 1999;35(1):105–106. [PMID: 10234648] (A 20-month-old girl with status epilepticus after camphor ingestion was treated successfully with intubation, diazepam, and phenobarbital.)

► CARBAMAZEPINE

Thomas E. Kearney, PharmD

Carbamazepine, an iminostilbene compound, was introduced in the United States in 1974 for the treatment of trigeminal neuralgia. It has become a first-line drug for the treatment of generalized and partial complex seizure disorders, and has found expanded use for pain syndromes, psychiatric illnesses, and drug withdrawal reactions.

I. Mechanism of toxicity

- A.** Most toxic manifestations appear to be related to its CNS-depressant and anticholinergic effects. It also alters cerebellar-vestibular brainstem function.
- B.** In addition, presumably because its chemical structure is similar to that of the tricyclic antidepressant imipramine, acute carbamazepine overdose can cause seizures and cardiac conduction disturbances.
- C. Pharmacokinetics.** Carbamazepine is slowly and erratically absorbed from the gastrointestinal tract, and peak levels may be delayed for 6–24 hours, particularly after an overdose (continued absorption for up to 96 hours has been reported with extended-release preparations). It is 75–78% protein bound with a volume of distribution (V_d) of approximately 1.4 L/kg (up to 3 L/kg after overdose). Up to 28% of a dose is eliminated in the feces, and there is enterohepatic recycling. The parent drug is metabolized by cytochrome P-450, and 40% is converted to its 10,11-epoxide, which is as active as the parent compound. The elimination half-life is variable and is subject to autoinduction of P-450 enzymes; the half-life of carbamazepine is approximately 18–55 hours (initially) to 5–26 hours (with chronic use). The half-life of the epoxide metabolite is approximately 5–10 hours.

- II. Toxic dose.** Acute ingestion of more than 10 mg/kg could result in a blood level above the therapeutic range of 4–12 mg/L. The recommended maximum daily dose is 1.6–2.4 g in adults (35 mg/kg/day in children). Death has occurred after adult ingestion of 3.2–60 g, but survival has been reported after an 80-g ingestion. Life-threatening toxicity occurred after ingestion of 5.8–10 g in adults and 2 g (148 mg/kg) in a 23-month-old child.

III. Clinical presentation

- A.** Ataxia, nystagmus, ophthalmoplegia, movement disorders (dyskinesia, dystonia), mydriasis, and sinus tachycardia are common with mild to moderate overdose. With more serious intoxication, myoclonus, seizures (including status epilepticus), hyperthermia, coma, and respiratory arrest may occur. Atrioventricular (AV) block and bradycardia have been reported, particularly in the elderly. Based on its structural similarity to tricyclic antidepressants, carbamazepine may cause QRS and QT interval prolongation and myocardial depression; however, in case reports of overdose, QRS widening rarely exceeds 100–120 msec and is usually transient.
- B.** After an acute overdose, manifestations of intoxication may be delayed for several hours because of erratic absorption. Cyclic coma and rebound relapse of symptoms may be caused by continued absorption from a tablet mass as well as enterohepatic circulation of the drug.
- C.** Chronic use has been associated with bone marrow depression, hepatitis, renal disease, cardiomyopathy, hyponatremia, and exfoliative dermatitis. Carbamazepine has also been implicated in rigidity-hyperthermia syndromes (eg, neuroleptic malignant syndrome and serotonin syndrome) in combination with other drugs.

- IV. Diagnosis** is based on a history of exposure and clinical signs such as ataxia, stupor, and tachycardia, along with elevated serum levels.

- A. Specific levels.** Obtain a stat serum carbamazepine level and repeat levels every 4–6 hours to rule out delayed or prolonged absorption.
 - 1. Serum levels greater than 10 mg/L are associated with ataxia and nystagmus. Serious intoxication (coma, respiratory depression, seizures) is likely with serum levels greater than 40 mg/L, although there is poor correlation between levels and severity of clinical effects.
 - 2. The epoxide metabolite may be produced in high concentrations after overdose. It is nearly equipotent, and may cross-react with some carbamazepine immunoassays to a variable extent.
 - 3. Carbamazepine can produce a false-positive test for tricyclic antidepressants on drug screening.
- B. Other useful laboratory studies** include CBC, electrolytes, glucose, arterial blood gases or oximetry, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat seizures (see p 22), coma (p 16), hyperthermia (p 21), and arrhythmias (pp 10–15) if they occur.
3. Asymptomatic patients should be observed for a minimum of 6 hours after ingestion, and for at least 12 hours if an extended-release preparation was ingested.

B. Specific drugs and antidotes. There is no specific antidote. Sodium bicarbonate (see p 419) is of unknown value for QRS prolongation. Physostigmine is **not** recommended for anticholinergic toxicity.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.
2. **Hospital.** Administer activated charcoal. Gastric lavage is not necessary after small to moderate ingestions if activated charcoal can be given promptly. For massive ingestions, consider additional doses of activated charcoal and possibly whole-bowel irrigation (see p 52).

D. Enhanced elimination. In contrast to tricyclic antidepressants, the volume of distribution of carbamazepine is small, making it accessible to enhanced removal procedures.

1. **Repeat-dose activated charcoal** is effective and may increase clearance by up to 50%. However, it may be difficult to perform safely in a patient with obtundation and ileus, and there is no demonstrated benefit on morbidity or mortality.
2. **Charcoal hemoperfusion** is highly effective and may be indicated for severe intoxication (eg, status epilepticus, cardiotoxicity, serum level > 60 mg/L) unresponsive to standard treatment. High-flux (also known as high-efficiency) **hemodialysis** is also reportedly effective.
3. Peritoneal dialysis does not effectively remove carbamazepine.
4. Plasma exchange has been used in children.

Spiller HA: Management of carbamazepine overdose. *Pediatr Emerg Care* 2001;17(6):452–456. [PMID: 11753195] (Review with extensive bibliography.)

Tapolyai M et al: Hemodialysis is as effective as hemoperfusion for drug removal in carbamazepine poisoning. *Nephron* 2002;90(2):213–215. [PMID: 11818708] (Repeated 3-hour high-flux hemodialysis treatments reduced serum CBZ levels by 27.7% and 25.3%.)

► CARBON DISULFIDE

Paul D. Blanc, MD, MSPH

Carbon disulfide is a volatile organic solvent, used mainly as a starting material in rayon manufacture in the viscose process. It was important historically in the cold vulcanization of rubber. Although no longer used in this form, carbon disulfide is still a major industrial precursor in rubber industry chemical synthesis and has a number of other industrial applications. Carbon disulfide is also widely used as a solvent in a variety of laboratory settings. Carbon disulfide is a metabolite of the drug disulfiram (see pp 186) and is a spontaneous breakdown by-product of the pesticide metam sodium.

I. Mechanism of toxicity. Carbon disulfide toxicity appears to involve disruption of a number of metabolic pathways in various organ systems, including but not limited to the central nervous system. Although key toxic effects have been attributed to the functional disruption of enzymes, especially in dopamine-dependent systems, carbon disulfide is widely reactive with a variety of biologic substrates.

II. Toxic dose

- A.** Carbon disulfide is highly volatile (vapor pressure 297 mm Hg), and inhalation is a major route of exposure. The OSHA permissible exposure limit (PEL) is 10 ppm (100 ppm, 30-minute peak), while the NIOSH recommended expo-

sure limit (REL) is substantially lower at 1 ppm. Carbon disulfide is also well absorbed through the skin.

- B. Carbon disulfide exposure via ingestion would be unusual, but if ingested would likely be very well absorbed. Chronic ingestion of therapeutic doses of disulfiram (200 mg per day) has been suspected to cause carbon disulfide–mediated toxicity, but this has not been firmly established.

III. Clinical presentation

- A. Acute carbon disulfide exposure can cause eye and skin irritation and CNS depression.
- B. Short-term (days to weeks) high-level exposure to carbon disulfide is associated with psychiatric manifestations ranging from mood change to frank delirium and psychosis.
- C. Chronic lower-level exposure can cause parkinsonism and other poorly reversible CNS impairments, optic neuritis, peripheral neuropathy, and atherosclerosis. Based on animal data, carbon disulfide exposure is likely to be associated with adverse reproductive outcomes.

- IV. **Diagnosis** of carbon disulfide toxicity is based on a history of exposure along with consistent signs and symptoms of one of its toxic manifestations. Industrial hygiene data documenting airborne exposure, if available, are useful diagnostically and in initiating protective measures.

- A. **Specific levels.** Biological monitoring for carbon disulfide is not routinely performed.

- B. **Other useful laboratory studies** can include nerve conduction studies if neuropathy is suspected and brain MRI/MRA to assess the central nervous system.

V. Treatment

- A. **Emergency and supportive measures.** Severe acute exposure would present as nonspecific CNS depression.

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Start an intravenous line and monitor the patient's vital signs and ECG closely.

- B. **Specific drugs and antidotes.** There are no specific antidotes for carbon disulfide.

- C. **Decontamination** after high-level exposure (see p 46).

1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
2. **Skin and eyes.** Remove contaminated clothing and wash exposed skin. Irrigate exposed eyes with copious amounts of tepid water or saline (see p 47).
3. **Ingestion.** Administer activated charcoal (see p 48).

- D. **Enhanced elimination.** There is no role for these procedures.

Frumkin H: Multiple system atrophy following chronic carbon disulfide exposure. *Environ Health Perspect* 1998;108:A110. [PMID: 9721261] (Case report with detailed review of the literature on carbon disulfide neurotoxicity.)

[PMID: 12070632] (Review of the extensive literature on adverse cardiovascular outcomes related to chronic carbon disulfide exposure.)

► CARBON MONOXIDE

Kent R. Olson, MD

Carbon monoxide (CO) is a colorless, odorless, tasteless, and nonirritating gas produced by the incomplete combustion of any carbon-containing material. Common sources of human exposure include smoke inhalation in fires, automobile exhaust

fumes, faulty or poorly ventilated charcoal, kerosene, or gas stoves, and, to a lesser extent, cigarette smoke and methylene chloride (see p 265). Carbon monoxide poisoning accounts for approximately 40,000 emergency department visits every year in the United States. Recently, several reports have described CO poisoning in children and adults riding in the back of pickup trucks with a camper shell.

I. Mechanism of toxicity. Toxicity is a consequence of cellular hypoxia and ischemia.

- A. CO binds to hemoglobin with an affinity 250 times that of oxygen, resulting in reduced oxyhemoglobin saturation and decreased blood oxygen-carrying capacity. In addition, the oxyhemoglobin dissociation curve is displaced to the left, impairing oxygen delivery at the tissues.
- B. CO may also directly inhibit cytochrome oxidase, further disrupting cellular function, and it is known to bind to myoglobin, possibly contributing to impaired myocardial contractility.
- C. In animal models of intoxication, damage is most severe in areas of the brain that are highly sensitive to ischemia and often correlates with the severity of systemic hypotension. Postanoxic injury appears to be complicated by lipid peroxidation, excessive release of excitatory neurotransmitters, and inflammatory changes, including adherence of neutrophils to cerebral vessels.
- D. Fetal hemoglobin is more sensitive to binding by CO, and fetal or neonatal levels may be higher than maternal levels.
- E. **Pharmacokinetics.** The carboxyhemoglobin complex gradually dissociates after removal from exposure. The approximate half-life of elimination of CO-Hgb during treatment with high-flow oxygen by tight-fitting mask or endotracheal tube is 74 minutes (range 24–148). In room air the approximate half-life is as much as 200 minutes, and during hyperbaric oxygen therapy it is as short as 12–20 minutes.

II. Toxic dose. The recommended workplace limit (ACGIH TLV-TWA) for carbon monoxide is 25 ppm as an 8-hour time-weighted average. The level considered immediately dangerous to life or health (IDLH) is 1200 ppm (0.12%). However, the *duration* of exposure is very important. While exposure to 1000 ppm (0.1%) will eventually result in 50% saturation of carboxyhemoglobin, it may take several hours to reach that level. In 1895 Haldane experimented on himself by breathing 2100 ppm CO for over an hour, and it was only after 34 minutes, when his level would have been approximately 25%, that he described a throbbing headache. Brief exposure to much higher levels may produce a more rapid rise in CO-Hgb.

III. Clinical presentation. Symptoms of intoxication are predominantly in organs with high oxygen consumption such as the brain and heart.

- A. The majority of patients complain of headache, dizziness, and nausea. Patients with coronary disease may experience angina or myocardial infarction. With more severe exposures, impaired thinking, syncope, coma, convulsions, cardiac arrhythmias, hypotension, and death may occur. Although blood carboxyhemoglobin levels may not correlate reliably with the severity of intoxication, levels greater than 25% are considered significant and levels greater than 40–50% are usually associated with obvious intoxication.
- B. Survivors of serious poisoning may suffer numerous overt neurologic sequelae consistent with a hypoxic-ischemic insult, ranging from gross deficits such as parkinsonism and a persistent vegetative state to subtler personality and memory disorders. Various studies suggest that the incidence of subtle neuropsychiatric sequelae such as impaired memory and concentration and mood disorders may be as high as 47%.
- C. Exposure during pregnancy may result in fetal demise.

IV. Diagnosis is not difficult if there is a history of exposure (eg, the patient was found in a car in a locked garage) but may be elusive if not suspected in less obvious cases. There are no specific reliable clinical findings; cherry red skin coloration or bright red venous blood is highly suggestive but not frequently noted. The routine arterial blood gas machine measures the partial pressure of oxygen

dissolved in plasma (pO_2), but oxygen saturation is calculated from the pO_2 and is therefore unreliable in patients with CO poisoning. Pulse oximetry also gives falsely normal readings, because it is unable to distinguish between oxyhemoglobin and carboxyhemoglobin.

A. Specific levels. Obtain a specific carboxyhemoglobin concentration. Persistence of fetal hemoglobin may produce falsely elevated carboxyhemoglobin levels in young infants.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, ECG, and pregnancy tests. Metabolic acidosis suggests more serious poisoning. With smoke inhalation, obtain blood cyanide level and methemoglobin concentration.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). If smoke inhalation has also occurred, consider early intubation for airway protection.
2. Treat coma (p 19) and seizures (p 22) if they occur.
3. Continuously monitor the ECG for several hours after exposure.
4. Because smoke often contains other toxic gases, consider the possibility of cyanide poisoning (see p 177), methemoglobinemia (p 261), and irritant gas injury (p 213).

B. Specific drugs and antidotes. Administer **oxygen** in the highest possible concentration (100%). Breathing 100% oxygen speeds the elimination of CO from hemoglobin to approximately 1 hour, compared with 6 hours in room air. Use a tight-fitting mask and high-flow oxygen with a reservoir (nonrebreather) or administer the oxygen by endotracheal tube. Treat until the carboxyhemoglobin level is less than 5%. Consider **hyperbaric oxygen** in severe cases (see below).

C. Decontamination. Remove the patient immediately from exposure and give supplemental oxygen. Rescuers exposed to potentially high concentrations of CO should wear self-contained breathing apparatus.

D. Enhanced elimination. Hyperbaric oxygen provides 100% oxygen under 2–3 atmospheres of pressure and can enhance elimination of CO (half-life reduced to 20–30 minutes). In animal models it reduces lipid peroxidation and neutrophil activation, and in a recent randomized controlled trial in humans it reduced the incidence of subtle cognitive sequelae compared with normobaric 100% oxygen. HBO may be useful in patients with severe intoxication, especially when there is ready access to a chamber. It remains unclear whether its benefits over normobaric oxygen apply to victims presenting many hours after exposure or with milder degrees of intoxication. Consult a regional poison control center ([800] 222-1222) for advice and for the location of nearby hyperbaric chambers. See Table II–19 for a list of proposed indications for HBO.

TABLE II–19. PROPOSED INDICATIONS FOR HYPERBARIC OXYGEN TREATMENT FOR CARBON MONOXIDE POISONING^a

Presence of the following^{b,c}:

Loss of consciousness

COHgb > 25%

Age > 50 years

Metabolic acidosis (base excess less than 2 mEq/L)

^aFrom Weaver LK et al: Outcome of acute carbon monoxide poisoning treated with hyperbaric or normobaric oxygen (Abstract). *Undersea Hyperb Med* 2001; 28(suppl):15.

^bIn patients with *none* of these criteria, HBO did *not* improve outcome.

^cAbnormal cerebellar findings also correlated with risk of neurocognitive sequelae

Weaver LK et al: Hyperbaric oxygen for acute carbon monoxide poisoning. *N Engl J Med* 2002;347(14):1057–1067. [PMID: 12362006] (Randomized, double-blind, controlled trial using sham HBO treatments for the normobaric group found a small but significant reduction in cognitive sequelae at 6 weeks after treatment.)

► CARBON TETRACHLORIDE AND CHLOROFORM

Frederick Fung, MD, MS

Carbon tetrachloride (CCl_4 , tetrachloromethane) was once widely used as a dry cleaning solvent, degreaser, spot remover, fire extinguisher agent, and anthelmintic. Because of its liver toxicity and known carcinogenicity in animals, its role has become limited; it is now used mainly as an intermediate in chemical manufacturing.

Chloroform (trichloromethane) is a chlorinated hydrocarbon solvent used as a raw material in the production of freon and as an extractant and solvent in the chemical and pharmaceutical industry. Because of its hepatic toxicity, it is no longer used as a general anesthetic or anthelmintic agent. Chronic low-level exposure may occur in some municipal water supplies owing to chlorination of biologic methanes (trihalomethanes).

I. Mechanism of toxicity. Carbon tetrachloride and chloroform are CNS depressants and potent hepatic and renal toxins. They may also increase the sensitivity of the myocardium to arrhythmogenic effects of catecholamines. The mechanism of hepatic and renal toxicity is thought to be a result of a toxic free-radical intermediate of cytochrome P-450 metabolism. (Bioactivation of CCl_4 has become a model for chemical toxicity induced by free radicals.) Chronic use of metabolic enzyme inducers such as phenobarbital and ethanol increases the toxicity of carbon tetrachloride. Carbon tetrachloride is a known animal and suspected human carcinogen. Chloroform is embryotoxic and an animal carcinogen.

II. Toxic dose

A. Toxicity from inhalation is dependent on the concentration in air and the duration of exposure.

- 1. Carbon tetrachloride.** Symptoms have occurred after exposure to 160 ppm for 30 minutes. The recommended workplace limit (ACGIH TLV-TWA) is 5 ppm as an 8-hour time-weighted average, and the air level considered immediately dangerous to life or health (IDLH) is 200 ppm.
- 2. Chloroform.** The air level considered immediately dangerous to life or health (IDLH) is 500 ppm. The recommended workplace limit (ACGIH TLV-TWA) is 10 ppm as an 8-hour time-weighted average.

B. Ingestion

- 1. Carbon tetrachloride.** Ingestion of as little as 5 mL has been reported to be fatal.
- 2. Chloroform.** The fatal **oral** dose may be as little as 10 mL, although survival after ingestion of more than 100 mL has been reported. The oral LD_{50} in rats is 2000 mg/kg.

III. Clinical presentation

- A. Persons exposed to carbon tetrachloride or chloroform from acute inhalation, skin absorption, or ingestion** may present with nausea, vomiting, headache, dizziness, and confusion. Mucous membrane irritation is also seen with ingestion or inhalation. With serious intoxication, respiratory arrest, cardiac arrhythmias, and coma may occur.
- B. Severe and sometimes fatal renal and hepatic damage** may become apparent after 1–3 days.
- C. Skin or eye contact** results in irritation and a defatting type dermatitis.

IV. Diagnosis is based on a history of exposure and the clinical presentation of mucous membrane irritation, CNS depression, arrhythmias, and hepatic necrosis. Carbon tetrachloride is radiopaque and may be visible on abdominal x-ray after acute ingestion.

- A. Specific levels.** Blood, urine, or breath concentrations may document exposure but are rarely available and are not useful for acute management. Qualitative urine screening for chlorinated hydrocarbons (Fujiwara test) may be positive after massive overdose.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, prothrombin time (PT), and ECG monitoring.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat coma (p 19) and arrhythmias (pp 12–15) if they occur. **Caution:** avoid use of epinephrine or other sympathomimetic amines because they may induce or aggravate arrhythmias. Tachyarrhythmias caused by increased myocardial sensitivity may be treated with **propranolol**, 1–2 mg IV in adults (see p 496), or **esmolol**, 0.025–0.1 mg/kg/min IV (see p 443). Monitor patients for at least 4–6 hours after exposure, and longer if symptomatic.
- B. Specific treatment. N-acetylcysteine** (NAC; see p 405) may minimize hepatic and renal toxicity by providing a scavenger for the toxic intermediate. Although its use for carbon tetrachloride or chloroform poisoning has not been studied in humans, acetylcysteine is widely used without serious side effects for treatment of acetaminophen overdose. If possible, it should be given within the first 12 hours after exposure. Animal studies also suggest possible roles for cimetidine, calcium channel blockers, and hyperbaric oxygen in reducing hepatic injury, but there is insufficient human experience with these treatments.
- C. Decontamination** (see p 46)
1. **Inhalation.** Remove from exposure and give supplemental oxygen, if available.
 2. **Skin and eyes.** Remove contaminated clothing and wash affected skin with copious soap and water. Irrigate exposed eyes with copious saline or water.
 3. **Ingestion**
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting with ipecac because of the risk of abrupt onset of coma.
 - b. **Hospital.** Perform gastric lavage, and administer activated charcoal.
- D. Enhanced elimination.** There is no role for dialysis, hemoperfusion, or other enhanced removal procedures.

Risse Met al: Multiple homicides as a result of chloroform poisoning: case report and experimental study. *Forensic Sci Int* 2001;124(2–3):209–213. [PMID: 11792514] (Report and forensic analysis discussion of 2 episodes of homicidal poisoning by chloroform involving 5 victims.)

► CARDIAC GLYCOSIDES

Neal L. Benowitz, MD

Cardiac glycosides are found in several plants, including oleander, foxglove, lily of the valley, red squill, and rhododendron, and in toad venom (*Bufo* spp, which may be found in some Chinese herbal medications). Cardiac glycosides are used therapeutically in tablet form as digoxin and digitoxin. Digoxin is also available in liquid-filled capsules with greater bioavailability.

I. Mechanism of toxicity

- A. Cardiac glycosides** inhibit the function of the sodium-potassium-ATPase pump. After acute overdose, this results in hyperkalemia (with chronic intoxication, the serum potassium level is usually normal or low owing to concurrent diuretic therapy).

- B. Vagal tone is potentiated, and sinus and atrioventricular (AV) node conduction velocity is decreased.
 - C. Automaticity in Purkinje fibers is increased due to accumulation of intracellular calcium.
 - D. **Pharmacokinetics.** The bioavailability of digoxin ranges from 60–80%; for digitoxin more than 90% is absorbed. The volume of distribution (Vd) of digoxin is very large (5–10 L/kg), whereas for digitoxin the Vd is small (about 0.5 L/kg). Peak effects occur after a delay of 6–12 hours. The elimination half-life of digoxin is 30–50 hours, and for digitoxin is 5–8 days (owing to enterohepatic recirculation). (See also Table II–59, p 381.)
- II. **Toxic dose.** Acute ingestion of as little as 1 mg of digoxin in a child or 3 mg of digoxin in an adult can result in serum concentrations well above the therapeutic range. More than these amounts of digoxin and other cardiac glycosides may be found in just a few leaves of oleander or foxglove. Generally, children appear to be more resistant than adults to the cardiotoxic effects of cardiac glycosides.
- III. **Clinical presentation.** Intoxication may occur after acute accidental or suicidal ingestion or with chronic therapy. Signs and symptoms depend on the chronicity of the intoxication.
- A. With **acute overdose**, vomiting, hyperkalemia, sinus bradycardia, sinoatrial arrest, and second- or third-degree AV block are common. Ventricular tachycardia or fibrillation may occur.
 - B. With **chronic intoxication**, visual disturbances, weakness, sinus bradycardia, atrial fibrillation with slowed ventricular response rate or junctional escape rhythm, and ventricular arrhythmias (ventricular bigeminy or trigeminy, ventricular tachycardia, bidirectional tachycardia, and ventricular fibrillation) are common. Accelerated junctional tachycardia and paroxysmal atrial tachycardia with block are frequently seen. Hypokalemia and hypomagnesemia from chronic diuretic use may be evident and appear to worsen the tachyarrhythmias.
- IV. **Diagnosis** is based on a history of recent overdose or characteristic arrhythmias (eg, bidirectional tachycardia and accelerated junctional rhythm) in a patient receiving chronic therapy. Hyperkalemia suggests acute ingestion but may also be seen with very severe chronic poisoning. Serum potassium levels higher than 5.5 mEq/L are associated with severe poisoning.
- A. **Specific levels.** Stat serum digoxin or digitoxin levels are recommended, although they may not correlate accurately with severity of intoxication. This is especially true after acute ingestion, when the serum level is high for 6–12 hours before tissue distribution is complete. After use of digitalis-specific antibodies, the radioimmunoassay digoxin level is falsely markedly elevated. Therapeutic levels of digoxin are 0.5–2 ng/mL; of digitoxin, 10–30 ng/mL.
 - B. **Other useful laboratory studies** include electrolytes, BUN, creatinine, serum magnesium, and ECG and ECG monitoring.
- V. **Treatment**
- A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Monitor the patient closely for at least 12–24 hours after significant ingestion because of delayed tissue distribution.
 3. Treat **hyperkalemia** (see p 37), if greater than 5.5 mEq/L, with sodium bicarbonate (1 mEq/kg), glucose (0.5 g/kg IV) with insulin (0.1 U/kg IV), or sodium polystyrene sulfonate (Kayexalate, 0.5 g/kg PO). Do **not** use calcium; it may worsen ventricular arrhythmias. Mild hyperkalemia may actually protect against tachyarrhythmias.
 4. Treat **bradycardia** or **heart block** with atropine, 0.5–2 mg IV (see p 412); a temporary pacemaker may be needed for persistent symptomatic bradycardia.
 5. **Ventricular tachyarrhythmias** may respond to lidocaine (see p 462) or phenytoin (p 488), or to correction of low potassium or magnesium. Avoid quinidine, procainamide, and other type Ia or type Ic antiarrhythmic drugs.

B. Specific drugs and antidotes. Fab fragments of **digoxin-specific antibodies** (Digibind) are indicated for significant poisoning (eg, severe hyperkalemia and symptomatic arrhythmias not responsive to drugs described above) and possibly for prophylactic treatment in a massive oral overdose with high serum levels. Digibind rapidly binds to digoxin and, to a lesser extent, digitoxin and other cardiac glycosides. The inactive complex that is formed is rapidly excreted in the urine. Details of dose calculation and infusion rate are given on p 434.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination

1. Because of its large volume of distribution, **digoxin** is not effectively removed by dialysis or hemoperfusion. Repeat-dose activated charcoal may be useful in patients with severe renal insufficiency, in whom clearance of digoxin is markedly diminished.

2. **Digitoxin** has a small volume of distribution and also undergoes extensive enterohepatic recirculation, and its elimination can be markedly enhanced by repeat-dose charcoal.

Eddleston M et al: Acute yellow oleander (*Thevetia peruviana*) poisoning: cardiac arrhythmias, electrolyte disturbances, and serum cardiac glycoside concentrations on presentation to hospital. *Heart* 2000 Mar;83(3):301–306. ► CAUSTIC AND CORROSIVE AGENTS

Walter H. Mullen, PharmD

A wide variety of chemical and physical agents may cause corrosive injury. These include mineral and organic acids, alkalis, oxidizing agents, denaturants, some hydrocarbons, and agents causing exothermic reactions. Although the mechanism and the severity of injury may vary, the consequences of mucosal damage and permanent scarring are shared by all agents.

Button batteries are small disk-shaped batteries used in watches, calculators, and cameras. They contain caustic metal salts such as mercuric chloride that may cause corrosive injury.

I. Mechanism of toxicity

A. Acids cause an immediate coagulation-type necrosis that creates an eschar, which tends to self-limit further damage.

B. In contrast, **alkalis** (eg, Drano) cause a liquefactive necrosis with saponification and continued penetration into deeper tissues, resulting in extensive damage.

C. Other agents may act by alkylating, oxidizing, reducing, or denaturing cellular proteins or by defatting surface tissues.

D. Button batteries cause injury by corrosive effects resulting from leakage of the corrosive metal salts, by direct impaction of the disk-shaped foreign body, and possibly by local discharge of electrical current at the site of impaction.

II. Toxic dose. There is no specific toxic dose or level, because the concentration of corrosive solutions and the potency of caustic effects vary widely. The concentration or the pH of the solution may indicate the potential for serious injury. For

alkalis, the titratable alkalinity (concentration of the base) is a better predictor of corrosive effect than the pH.

III. Clinical presentation

- A. Inhalation** of corrosive gases (eg, chlorine or ammonia) may cause upper respiratory tract injury, with stridor, hoarseness, wheezing, and noncardiogenic pulmonary edema. Pulmonary symptoms may be delayed after exposure to gases with low water solubility (eg, nitrogen dioxide or phosgene; see p 213).
- B. Eye or skin** exposure to corrosive agents usually results in immediate pain and redness, followed by blistering. Conjunctivitis and lacrimation are common. Serious full-thickness burns and blindness can occur.
- C. Ingestion** of corrosives can cause oral pain, dysphagia, drooling, and pain in the throat, chest, or abdomen. Esophageal or gastric perforation may occur, manifested by severe chest or abdominal pain, signs of peritoneal irritation, or pancreatitis. Free air may be visible in the mediastinum or abdomen on x-ray. Hematemesis and shock may occur. Systemic acidosis has been reported after acid ingestion and may be partly caused by absorption of hydrogen ions. Scarring of the esophagus or stomach may result in permanent stricture formation and chronic dysphagia.
- D. Systemic toxicity** can occur after inhalation, skin exposure, or ingestion of a variety of agents (Table II–20).
- E. Button batteries** usually cause serious injury only if they become impacted in the esophagus, leading to perforation into the aorta or mediastinum. Most cases involve large (25-mm diameter) batteries. If button batteries reach the stomach without impaction in the esophagus, they nearly always pass uneventfully via the stools within several days.

IV. Diagnosis is based on a history of exposure to a corrosive agent and characteristic findings of skin, eye, or mucosal irritation or redness and the presence of injury to the gastrointestinal tract. Victims with oral or esophageal injury nearly always have drooling or pain on swallowing.

- A. Endoscopy.** Esophageal or gastric injury is unlikely after ingestion if the patient is completely asymptomatic, but studies have repeatedly shown that a small number of patients will have injury in the absence of oral burns or obvious dysphagia. For this reason, many authorities recommend endoscopy for all patients regardless of symptoms.

TABLE II–20. EXAMPLES OF SYSTEMIC SYMPTOMS FROM CORROSIVE AGENTS^a

Corrosive Agent	Systemic Symptoms
Formaldehyde	Metabolic acidosis; formate poisoning (see p 207)
Hydrofluoric acid	Hypocalcemia; hyperkalemia (see p 221)
Methylene chloride	CNS depression; cardiac arrhythmias; converted to carbon monoxide (see p 265)
Oxalic acid	Hypocalcemia; renal failure (see p 295)
Paraquat	Pulmonary fibrosis (see p 296)
Permanganate	Methemoglobinemia (see p 261)
Phenol	Seizures; coma; hepatic and renal damage (see p 302)
Phosphorus	Hepatic and renal injury (see p 307)
Picric acid	Renal injury
Silver nitrate	Methemoglobinemia (see p 261)
Tannic acid	Hepatic injury

^aReference: Edelman PA: Chemical and electrical burns, pages 183–202. In *Management of the Burned Patient*, Achauer BM (editor). Appleton & Lange, 1987.

- B. X-rays** of the chest and abdomen will usually reveal impacted button batteries. X-rays may also demonstrate air in the mediastinum from esophageal perforation or free abdominal air from gastric perforation.
- C. Specific levels.** See specific chemical. Urine mercury levels have been reported to be elevated after button battery ingestion.
- D. Other useful laboratory studies** include CBC, electrolytes, glucose, arterial blood gases, chest x-ray, and upright abdominal x-ray.

V. Treatment

A. Emergency and supportive measures

- 1. Inhalation.** Give supplemental oxygen, and observe closely for signs of progressive airway obstruction or noncardiogenic pulmonary edema (see pp 6–7).
- 2. Ingestion**
 - a.** Immediately give water or milk to drink.
 - b.** If esophageal or gastric perforation is suspected, obtain immediate surgical or endoscopic consultation.

B. Specific drugs and antidotes. For most agents, there is no specific antidote. (See p 221 for hydrofluoric acid burns and p 302 for phenol burns.) In the past, corticosteroids were used by many clinicians in the hope of reducing scarring, but this treatment has been proved ineffective. Moreover, steroids may be harmful in the patient with perforation because they mask early signs of inflammation and inhibit resistance to infection.

C. Decontamination (see p 46). **Caution:** Rescuers should use appropriate respiratory and skin-protective equipment.

- 1. Inhalation.** Remove from exposure; give supplemental oxygen if available.
- 2. Skin and eyes.** Remove all clothing; wash skin and irrigate eyes with copious water or saline.
- 3. Ingestion**
 - a. Prehospital.** Immediately give water or milk to drink. Do **not** induce vomiting or give pH-neutralizing solutions (eg, dilute vinegar or bicarbonate).
 - b. Hospital. Gastric lavage** to remove the corrosive material is controversial but is probably beneficial in acute liquid corrosive ingestion, and it will be required before endoscopy anyway. Use a soft flexible tube and lavage with repeated aliquots of water or saline, frequently checking the pH of the washings.
 - c.** In general, do **not** give activated charcoal, as it may interfere with visibility at endoscopy. Charcoal may be appropriate if the ingested agent can cause significant systemic toxicity.
 - d. Button batteries** lodged in the esophagus must be removed immediately by endoscopy to prevent rapid perforation. Batteries in the stomach or intestine should not be removed unless signs of perforation or obstruction develop.

D. Enhanced elimination. In general, there is no role for any of these procedures (see specific chemical).

Hugh TB, Kelly MD: Corrosive ingestion and the surgeon. *J Am Coll Surg* 1999;189(5):508–522. Erratum in: *J Am Coll Surg* 2000;190(1):102. [PMID: 10549740] (Review of management of corrosive ingestions including detailed surgical interventions.)

► CHLORATES

Thomas R. Sands, PharmD

Potassium chlorate is a component of some match heads; barium chlorate (see also p 127) is used in the manufacture of fireworks and explosives; sodium chlorate is still a major ingredient of some weed killers used in commercial agriculture; and other

chlorate salts are used in dye production. Safer and more effective compounds have replaced chlorate in toothpaste and antiseptic mouthwashes. Chlorate poisoning is similar to bromate intoxication (see p 138), but chlorates are more likely to cause intravascular hemolysis and methemoglobinemia.

- I. **Mechanism of toxicity.** Chlorates are potent oxidizing agents and also attack sulfhydryl groups, particularly in red blood cells and the kidneys. Chlorates cause methemoglobin formation as well as increased red blood cell membrane fragility, which may result in intravascular hemolysis. Renal failure is probably caused by a combination of direct cellular toxicity and hemolysis.
- II. **Toxic dose.** The minimum toxic dose in children is not established, but is estimated to range from 1 g in infants to 5 g in older children. Children may ingest up to 1–2 matchbooks without toxic effect (each match head may contain 10–12 mg of chlorate). The adult lethal dose was estimated to be 7.5 g in one case but is probably closer to 20–35 g. A 26-year-old woman survived a 150- to 200-g ingestion.
- III. **Clinical presentation.** Within a few minutes to hours after ingestion, abdominal pain, vomiting, and diarrhea may occur. Methemoglobinemia is common (see p 261). Massive hemolysis, hemoglobinuria, and acute tubular necrosis may occur over 1–2 days after ingestion. Coagulopathy and hepatic injury have been described.
- IV. **Diagnosis** is usually based on a history of exposure and the presence of methemoglobinemia and hemolysis.
 - A. **Specific levels.** Blood levels are not available.
 - B. **Other useful laboratory studies** include CBC, haptoglobin, plasma free hemoglobin, electrolytes, glucose, BUN, creatinine, bilirubin, methemoglobin level, prothrombin time (PT), liver transaminases, and urinalysis.
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat coma (see p 19), hemolysis, hyperkalemia (p 37), and renal (p 39) or hepatic failure (p 40) if they occur.
 3. Massive hemolysis may require blood transfusions. To prevent renal failure resulting from deposition of free hemoglobin in the kidney tubules, administer intravenous fluids and sodium bicarbonate.
 - B. **Specific drugs and antidotes**
 1. Treat methemoglobinemia with **methylene blue** (see p 466), 1–2 mg/kg (0.1–0.2 mL/kg) of 1% solution. Methylene blue is reportedly most effective when used early in mild cases, but has poor effectiveness in severe cases where hemolysis has already occurred.
 2. Intravenous **sodium thiosulfate** (see p 505) may inactivate the chlorate ion and has been reported successful in anecdotal reports. However, this treatment has not been clinically tested. Administration as a lavage fluid may potentially produce some hydrogen sulfide, and so is contraindicated.
 - C. **Decontamination** (see p 46)
 1. **Prehospital.** Administer activated charcoal, if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49). **Note:** Spontaneous vomiting is common after significant ingestion.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary after small ingestions if activated charcoal can be given promptly.
 - D. **Enhanced elimination.** Chlorates are eliminated mainly through the kidney; elimination may be hastened by hemodialysis, especially in patients with renal insufficiency. Exchange transfusion and peritoneal dialysis have been used in a few cases.

worker with severe hypotension, hemolysis, and methemoglobinemia after massive oral ingestion of chlorate.)

► CHLORINATED HYDROCARBON PESTICIDES

Darren H. Lew, PharmD, and Shelly Lam, PharmD

Chlorinated hydrocarbon pesticides are widely used in agriculture, structural pest control, and malaria control programs around the world. Lindane is used medicinally for the treatment of lice and scabies. Chlorinated hydrocarbons are of major toxicologic concern, and many (eg, DDT and chlordane) are now banned from commercial use because they persist in the environment and accumulate in biologic systems. In 2002, sale of lindane was banned in California.

I. Mechanism of toxicity

A. Chlorinated hydrocarbons are neurotoxins that interfere with transmission of nerve impulses, especially in the brain, resulting in behavioral changes, involuntary muscle activity, and depression of the respiratory center. They may also sensitize the myocardium to arrhythmogenic effects of catecholamines, and many can cause liver or renal injury, possibly owing to generation of toxic metabolites. In addition, some chlorinated hydrocarbons may be carcinogenic.

B. Pharmacokinetics. Chlorinated hydrocarbons are well absorbed from the gastrointestinal tract, across the skin, and by inhalation. They are highly lipid soluble and accumulate with repeated exposure. Elimination does not follow first-order kinetics; compounds are slowly released from body stores over days to several months or years.

II. Toxic dose. The acute toxic doses of these compounds are highly variable, and reports of acute human poisonings are limited. Table II-21 ranks the relative toxicity of several common compounds.

A. Ingestion of as little as 1 g of lindane can produce seizures in a child, and 10–30 g is considered lethal in an adult. The estimated adult lethal oral doses of aldrin and chlordane are 3–7 g each; of dieldrin, 2–5 g. A 49-year-old man died after ingesting 12 g of endrin. A 20-year-old man survived a 60-g endosulfan ingestion but was left with a chronic seizure disorder.

B. Skin absorption is a significant route of exposure, especially with aldrin, dieldrin, and endrin. Extensive or repeated (as little as 2 applications on 2 successive days) whole-body application of lindane to infants has resulted in seizures and death.

III. Clinical presentation. Shortly after acute ingestion, nausea and vomiting occur, followed by paresthesias of the tongue, lips, and face; confusion; tremor; obtundation; coma; seizures; and respiratory depression. Because chlorinated hydrocarbons are highly lipid soluble, the duration of toxicity may be prolonged.

A. Recurrent or delayed-onset seizures have been reported.

TABLE II-21. COMMON CHLORINATED HYDROCARBONS

Low Toxicity (animal oral LD ₅₀ > 1 g/kg)	Moderately Toxic (animal oral LD ₅₀ > 50 mg/kg)	Highly Toxic (animal oral LD ₅₀ < 50 mg/kg)
Ethylan (Perthane)	Chlordane	Aldrin
Hexachlorobenzene	DDT	Dieldrin
Methoxychlor	Heptachlor	Endrin
	Kepone	Endosulfan
	Lindane	
	Mirex	
	Toxaphene	

- B. Arrhythmias may occur owing to myocardial sensitivity to catecholamines.
 - C. Metabolic acidosis may occur.
 - D. Signs of hepatitis or renal injury may develop.
 - E. Hematopoietic dyscrasias can develop late.
- IV. **Diagnosis** is based on the history of exposure and clinical presentation.
- A. **Specific levels.** Chlorinated hydrocarbons can be measured in the serum, but levels are not routinely available.
 - B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, hepatic transaminases, prothrombin time (PT), and ECG monitoring.
- V. **Treatment**
- A. **Emergency and supportive measures**
 - 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen. As most liquid products are formulated in organic solvents, observe for evidence of pulmonary aspiration (see Hydrocarbons, p 219).
 - 2. Treat seizures (p 22), coma (p 19), and respiratory depression (p 6) if they occur. Ventricular arrhythmias may respond to beta-adrenergic blockers such as propranolol (p 496) or esmolol (see p 443).
 - 3. Attach an electrocardiographic monitor, and observe the patient for at least 6–8 hours.
 - B. **Specific drugs and antidotes.** There is no specific antidote.
 - C. **Decontamination** (see p 46)
 - 1. **Skin and eyes.** Remove contaminated clothing and wash affected skin with copious soap and water, including hair and nails. Irrigate exposed eyes with copious tepid water or saline. Rescuers must take precautions to avoid personal exposure.
 - 2. **Ingestion**
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of an abrupt onset of seizures.
 - b. **Hospital.** Administer activated charcoal. Consider gastric lavage for large ingestions.
 - D. **Enhanced elimination** (see p 50)
 - 1. Repeat-dose activated charcoal or cholestyramine resin may be administered to enhance elimination by interrupting enterohepatic circulation.
 - 2. Exchange transfusion, peritoneal dialysis, hemodialysis, and hemoperfusion are not likely to be beneficial because of the large volume of distribution of these chemicals.

Nordt SP, Chew G: Acute lindane poisoning in three children. *J Emerg Med* 2000;18(1):51–53. [PMID: 10645838] (Inadvertent oral administration to three children. One had a single seizure; the other two were nauseated, listless, and poorly responsive.)

► CHLORINE

R. Steven Tharratt, MD

Chlorine is a heavier-than-air, yellowish-green gas with an irritating odor. It is used widely in chemical manufacturing, bleaching, and (as hypochlorite) in swimming pool disinfectant and cleaning agents. **Hypochlorite** is an aqueous solution produced by the reaction of chlorine gas with water; most household bleach solutions contain 3–5% hypochlorite; swimming pool disinfectants and industrial strength cleaners may contain up to 20% hypochlorite. The addition of acid to hypochlorite solution may release chlorine gas. The addition of ammonia to hypochlorite solution may release chloramine, a gas with properties similar to those of chlorine.

- I. **Mechanism of toxicity.** Chlorine gas produces a corrosive effect on contact with moist tissues such as the eyes and upper respiratory tract. Exposure to aqueous

solutions causes corrosive injury to the eyes, skin, or gastrointestinal tract (see p 157). Chloramine is less water soluble and may produce more indolent or delayed irritation.

II. Toxic dose

A. Chlorine gas. The recommended workplace limit (ACGIH TLV-TWA) for chlorine gas is 0.5 ppm (1.5 mg/m³) as an 8-hour time-weighted average. The short-term exposure limit (STEL) is 1 ppm. The level considered immediately dangerous to life or health (IDLH) is 10 ppm.

B. Aqueous solutions. Dilute aqueous hypochlorite solutions (3–5%) commonly found in homes rarely cause serious burns but are moderately irritating. However, more concentrated industrial cleaners (20% hypochlorite) are much more likely to cause serious corrosive injury.

III. Clinical presentation

A. Inhalation of chlorine gas. Symptoms are rapid in onset owing to the relatively high water solubility of chlorine. Immediate burning of the eyes, nose, and throat occurs, accompanied by coughing. Wheezing may also occur, especially in patients with pre-existing bronchospastic disease. With serious exposure, upper-airway swelling may rapidly cause airway obstruction, preceded by croupy cough, hoarseness, and stridor. With massive exposure, noncardiogenic pulmonary edema (chemical pneumonitis) may also occur.

B. Skin or eye contact with gas or concentrated solution. Serious corrosive burns may occur. Manifestations are similar to those of other corrosive exposures (see p 157).

C. Ingestion of aqueous solutions. Immediate burning in the mouth and throat is common, but no further injury is expected after ingestion of 3–5% hypochlorite. With more concentrated solutions, serious esophageal and gastric burns may occur, and victims often have dysphagia, drooling, and severe throat, chest, and abdominal pain. Hematemesis and perforation of the esophagus or stomach may occur.

IV. Diagnosis is based on a history of exposure and description of the typical irritating odor, accompanied by irritative or corrosive effects on the eyes, skin, or upper respiratory or gastrointestinal tract.

A. Specific levels are not available.

B. Other useful laboratory studies include, with **ingestion**, CBC, electrolytes, and chest and abdominal x-rays; with **inhalation**, arterial blood gases or oximetry and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Inhalation of chlorine gas

a. Immediately give humidified supplemental oxygen. Observe carefully for signs of progressive upper-airway obstruction, and intubate the trachea if necessary (see pp 1–7).

b. Use bronchodilators for wheezing (see p 8), and treat noncardiogenic pulmonary edema (p 7) if it occurs.

2. Ingestion of hypochlorite solution. If a solution of 10% or greater has been ingested, or if there are any symptoms of corrosive injury (dysphagia, drooling, or pain), flexible endoscopy is recommended to evaluate for serious esophageal or gastric injury. Obtain chest and abdominal x-rays to look for mediastinal or intra-abdominal air, which suggests perforation.

B. Specific drugs and antidotes. There is no proved specific treatment for this or other common caustic burns or inhalations. The administration of corticosteroids is unproved and may be harmful in patients with perforation or serious infection.

C. Decontamination (see p 46)

1. Inhalation. Remove immediately from exposure, and give supplemental oxygen if available.

2. Skin and eyes. Remove contaminated clothing, and flush exposed skin immediately with copious water. Irrigate exposed eyes with water or saline.

3. Ingestion of hypochlorite solution

- a. **Prehospital.** Immediately give water by mouth. Do **not** induce vomiting.
- b. **Hospital.** Gastric lavage may be useful after concentrated liquid ingestion, in order to remove any corrosive material in the stomach and to prepare for endoscopy; use a small flexible tube to avoid injury to damaged mucosa.
- c. Do **not** use activated charcoal; it may obscure the endoscopist's view.

D. Enhanced elimination. There is no role for enhanced elimination.

Guloglu C et al: Acute accidental exposure to chlorine gas in the Southeast of Turkey: a study of 106 cases. *Environ Res* 2002;88(2):89–93. [PMID: 11908933] (Of the 106 patients seen in hospitals, 37 were severely affected. Humidified oxygen and beta-agonist bronchodilators were the most useful treatments.)

► CHLOROPHENOXY HERBICIDES

Michael A. O'Malley, MD, MPH

Chlorophenoxy compounds have been widely used as herbicides. Agent Orange was a mixture of the chlorophenoxy herbicides 2,4-D (dichlorophenoxyacetic acid) and 2,4,5-T (trichlorophenoxyacetic acid) that also contained small amounts of the highly toxic contaminant TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin; see p 184) derived from the process of manufacturing 2,4,5-T. Manufacture of 2,4-D by chlorination of phenol does not produce TCDD. Populations involved in manufacture or handling of 2,4,5-T may show elevated levels of TCDD on serum testing and overall increased rates of cancer compared to the general population.

There are 49 different formulations available in the United States, including 2,4-D salts (sodium, amine, alkylamine, and alkanolamine) and esters (propanoic acid, butanoic acid, and other alkoxy compounds). Concentrated formulations of 2,4-D esters are likely to contain petroleum solvents (identified on the "first aid" statement on the pesticide label); while these are considered "inert" ingredients because they are not pesticides, they may have their own innate toxicity (see Toluene and Xylene, p 357; and Hydrocarbons, p 219).

- I. **Mechanism of toxicity.** In plants, the compounds act as growth hormone stimulators. The mechanism of toxicity is unclear, but may involve mitochondrial injury. In animals, cell membrane damage, uncoupling of oxidative phosphorylation, and disruption of acetylcoenzyme A metabolism are found, widespread muscle damage occurs, and the cause of death is usually ventricular fibrillation. Massive rhabdomyolysis has been described in human cases.
- II. **Toxic dose.** Doses of 5 mg/kg of 2,4-D are reported to have no effect in human volunteer studies. The minimum toxic dose of 2,4-D in humans is 3–4 g or 40–50 mg/kg, and death has occurred after adult ingestion of 6.5 g. Less than 6% of 2,4-D applied to the skin is absorbed systemically, although dermal exposure may produce skin irritation. Less than 6% of 2,4-D applied to the skin is absorbed systemically, although the degree of dermal absorption may be less with salt formulations than with 2,4-D esters.
- III. **Clinical presentation**
 - A. **Acute ingestion.** Vomiting, abdominal pain, and diarrhea are common. Tachycardia, muscle weakness, and muscle spasms occur shortly after ingestion and may progress to profound muscle weakness and coma. Massive rhabdomyolysis, metabolic acidosis, and severe and intractable hypotension have been reported, resulting in death within 24 hours. Neurotoxic effects include ataxia, hypertonias, seizures and coma. Hepatitis and renal failure may occur.
 - B. **Dermal exposure** to 2,4-D may produce skin irritation. Exposures to formulations containing 2,4,5-T may also produce chloracne. Substantial dermal ex-

posure has been reported to cause a mixed sensory-peripheral neuropathy after a latent period.

IV. Diagnosis depends on a history of exposure and the presence of muscle weakness and elevated serum CPK.

A. Specific levels of 2,4-D can be measured but may not be available in a timely enough fashion to be of help in establishing the diagnosis. The elimination half-life of 2,4-D is 11.5 hours and more than 75% is excreted by 96 hours after ingestion. More than 80% is excreted in the urine unchanged.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, CPK, urinalysis (occult heme test positive in the presence of myoglobin), liver enzymes, 12-lead ECG, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), hypotension (p 16), and rhabdomyolysis (p 27) if they occur.
3. Monitor the patient closely for at least 6–12 hours after ingestion because of the potential for delayed onset of symptoms.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Administer activated charcoal, then perform gastric lavage. After lavage, give an additional dose of charcoal.
3. **Skin or eye exposure.** Remove contaminated clothing and wash affected areas.

D. Enhanced elimination. There is no proven role for these procedures, although **alkalinization of the urine** may promote excretion of 2,4-D. (As with other weak acids, alkalinization would be expected to promote ionization of the phenoxy acid and decrease reabsorption from the renal tubules.) **Hemodialysis** has been recommended based on limited clinical data showing clearances similar to alkaline diuresis. **Plasmapheresis** was reported effective in a pediatric case report involving polyneuropathy associated with 2,4-D ingestion.

Bradberry SM et al: Mechanisms of toxicity, clinical features, and management of acute chlorophenoxy herbicide poisoning: a review. *J Toxicol Clin Toxicol* 2000;38(2):111–122. [PMID: 10778907] (Thorough literature review.)

► CHLOROQUINE AND OTHER AMINOQUINOLINES

Neal L. Benowitz, MD

Chloroquine and other aminoquinolines are used in the prophylaxis or therapy of malaria and other parasitic diseases. Chloroquine and hydroxychloroquine are also used in the treatment of rheumatoid arthritis. Drugs in this class include chloroquine phosphate (Aralen™), amodiaquine hydrochloride (Camoquin™), hydroxychloroquine sulfate (Plaquenil™), mefloquine (Lariam™), primaquine phosphate, and quinacrine hydrochloride (Atabrine™). Chloroquine overdose is common, especially in countries where malaria is prevalent, and the mortality rate is 10–30%. Quinine toxicity is described on p 326.

I. Mechanism of toxicity

A. Chloroquine blocks the synthesis of DNA and RNA and also has some quinidine-like cardiotoxicity. Hydroxychloroquine has similar actions but is considerably less potent.

- B. Primaquine and quinacrine** are oxidizing agents and can cause methemoglobinemia or hemolytic anemia (especially in patients with glucose-6-phosphate dehydrogenase [G6PD] deficiency).
- C. Pharmacokinetics.** Chloroquine and related drugs are highly tissue-bound (volume of distribution [Vd] = 150–250 L/kg) and are eliminated very slowly from the body. The terminal half-life of chloroquine is 2 months. Primaquine is extensively metabolized with a half-life of 3–8 hours to an active metabolite that is eliminated much more slowly (half-life 22–30 hours) and can accumulate with chronic dosing. (See also Table II–59.)
- II. Toxic dose.** The therapeutic dose of chloroquine phosphate is 500 mg once a week for malaria prophylaxis or 2.5 g over 2 days for treatment of malaria. Deaths have been reported in children after doses as low as 300 mg; the lethal dose of chloroquine for an adult is estimated at 30–50 mg/kg.
- III. Clinical presentation**
- A. Mild to moderate chloroquine overdose** results in dizziness, nausea and vomiting, abdominal pain, headache and visual disturbances (sometimes including irreversible blindness), auditory disturbances (sometimes leading to deafness), agitation, and neuromuscular excitability.
- B. Severe chloroquine overdose** may cause convulsions, coma, shock, and respiratory or cardiac arrest. Quinidine-like cardiotoxicity may be seen, including sinoatrial arrest, depressed myocardial contractility, QRS or QT interval prolongation, heart block, and ventricular arrhythmias. Severe hypokalemia sometimes occurs and may contribute to arrhythmias.
- C. Primaquine and quinacrine** intoxication commonly cause gastrointestinal upset and may also cause severe methemoglobinemia (see p 261) or hemolysis; chronic treatment can cause ototoxicity and retinopathy.
- D. Amodiaquine** in therapeutic doses has caused severe and even fatal neutropenia.
- E. Mefloquine** in therapeutic use or overdose may cause dizziness, vertigo, hallucinations, psychosis, and seizures.
- IV. Diagnosis.** The findings of gastritis, visual disturbances, and neuromuscular excitability, especially if accompanied by hypotension, QRS or QT interval widening, or ventricular arrhythmias, should suggest chloroquine overdose. Hemolysis or methemoglobinemia should suggest primaquine or quinacrine overdose.
- A. Specific levels.** Chloroquine is usually not detected on comprehensive toxicology screening. Quantitative levels can be measured in blood but are not generally available. Because chloroquine is concentrated intracellularly, whole-blood measurements are fivefold higher than serum or plasma levels.
1. Plasma (trough) concentrations of 10–20 ng/mL (0.01–0.02 mg/L) are effective in the treatment of various types of malaria.
 2. Cardiotoxicity may be seen with serum levels of 1 mg/L (1000 ng/mL); serum levels reported in fatal cases have ranged from 1 to 210 mg/L (average, 60 mg/L).
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, and ECG and ECG monitoring. With **primaquine** or **quinacrine**, also include CBC, free plasma hemoglobin, and methemoglobin.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat seizures (see p 22), coma (p 19), hypotension (p 16), and methemoglobinemia (p 261) if they occur.
 3. Treat massive hemolysis with blood transfusions if needed, and prevent hemoglobin deposition in the kidney tubules by alkaline diuresis (as for rhabdomyolysis; see p 27).
 4. Continuously monitor the ECG for at least 6–8 hours.
- B. Specific drugs and antidotes**
1. Treat cardiotoxicity as for quinidine poisoning (see p 324) with **sodium bicarbonate** (see p 419), 1–2 mEq/kg IV.

2. **Epinephrine** infusion (see p 442) may be useful in treating hypotension via combined vasoconstrictor and inotropic actions. Dosing recommendations in one study were 0.25 mcg/kg/min, increasing by increments of 0.25 mcg/kg/min until adequate blood pressure was obtained, along with administration of high-dose diazepam (see below) and mechanical ventilation.
 3. High-dose **diazepam** (2 mg/kg IV, given over 30 minutes after endotracheal intubation and mechanical ventilation) has been reported to reduce mortality in animals and to ameliorate cardiotoxicity in human chloroquine poisonings. The mechanism of protection is unknown.
- C. Decontamination** (see p 47)
1. **Prehospital.** Administer activated charcoal if available. Do not induce vomiting.
 2. **Hospital.** Administer activated charcoal. Perform gastric lavage for significant ingestions (eg, > 30–50 mg/kg). Gastric emptying is probably not necessary after small ingestions if activated charcoal can be given promptly.
- D. Enhanced elimination.** Because of extensive tissue distribution, enhanced removal procedures are ineffective.

Marquardt K, Albertson T: Treatment of hydroxychloroquine overdose. *Am J Emerg Med* 2001;19(5):420–424. [PMID: 11555803] (Case report demonstrating hypotension, QRS prolongation, and hypokalemia; the authors provide a review of the literature and summary of recommended treatment.)

► CHROMIUM

Thomas J. Ferguson, MD, PhD

Chromium is a durable metal used in electroplating, paint pigments (chrome yellow), primers and corrosion inhibitors, wood preservatives, textile preservatives, and leather tanning agents. Chromium exposure may occur by inhalation, ingestion, or skin exposure. Although chromium can exist in a variety of oxidation states, most human exposures involve one of two types: trivalent (eg, chromic oxide, chromic sulfate) or hexavalent (eg, chromium trioxide, chromic anhydride, chromic acid, dichromate salts). Toxicity is most commonly associated with hexavalent compounds; however, fatalities have occurred after ingestion of compounds of either type, and chronic skin sensitivity is probably related to the trivalent form. Chromium picolinate is a trivalent chromium compound often promoted as a body-building agent.

I. Mechanism of toxicity

- A. Trivalent chromium** compounds are relatively insoluble and noncorrosive, and are less likely to be absorbed through intact skin. Biological toxicity is estimated to be 10- to 100-fold lower than for the hexavalent compounds.
- B. Hexavalent compounds** are powerful oxidizing agents and are corrosive to the airway, skin, mucous membranes, and gastrointestinal tract. Acute hemolysis and renal tubular necrosis may also occur. Chronic occupational exposure to less soluble hexavalent forms is associated with chronic bronchitis, dermatitis, and lung cancer.
- C. Chromic acid** is a strong acid, while some chromate salts are strong bases.

II. Toxic dose

- A. Inhalation.** The OSHA workplace permissible exposure limit (PEL, 8-hour time-weighted average) for chromic acid and hexavalent compounds is 0.05 mg/m³ (carcinogen). For bivalent and trivalent chromium the PEL is 0.5 mg/m³.
- B. Skin.** Chromium salts can cause skin burns, which may enhance systemic absorption, and death has occurred after a 10% surface area burn.
- C. Ingestion.** Life-threatening toxicity has occurred from ingestion of as little as 500 mg of hexavalent chromium. The estimated lethal dose of chromic acid is 1–2 g and of potassium dichromate, 6–8 g. Drinking water standards are set at 50 mcg/L (1 micromol/L) total chromium.

III. Clinical presentation

- A. Inhalation.** Acute inhalation can cause upper respiratory tract irritation, wheezing, and noncardiogenic pulmonary edema (which may be delayed for several hours to days after exposure). Chronic exposure to hexavalent compounds may lead to pulmonary sensitization, asthma, and cancer.
- B. Skin and eyes.** Acute contact may cause severe corneal injury, deep skin burns, and oral or esophageal burns. Hypersensitivity dermatitis may result. It has been estimated that chronic chromium exposure is responsible for about 8% of all cases of contact dermatitis. Nasal ulcers may also occur after chronic exposure.
- C. Ingestion.** Ingestion may cause acute hemorrhagic gastroenteritis; the resulting massive fluid and blood loss may cause shock and oliguric renal failure. Hemolysis, hepatitis, and cerebral edema have been reported. Chromates are capable of oxidizing hemoglobin, but clinically significant methemoglobinemia is relatively uncommon after acute overdose.

IV. Diagnosis is based on a history of exposure and clinical manifestations such as skin and mucous membrane burns, gastroenteritis, renal failure, or shock.

- A. Specific levels.** Blood levels are not useful in emergency management, nor are they widely available. Detection in the urine may confirm exposure; normal urine levels are less than 1 mcg/L.
- B. Other useful laboratory studies** include CBC, plasma free hemoglobin and haptoglobin (if hemolysis is suspected), electrolytes, glucose, BUN, creatinine, liver transaminases, urinalysis (for hemoglobin), arterial blood gas or pulse oximetry, methemoglobin, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. **Inhalation.** Give supplemental oxygen. Treat wheezing (see p 8), and monitor the victim closely for delayed-onset noncardiogenic pulmonary edema (p 7). Delays in the onset of pulmonary edema of up to 72 hours have been reported after inhalation of concentrated solutions of chromic acid.
2. **Ingestion**
 - a. Dilute immediately with water. Treat hemorrhagic gastroenteritis with aggressive fluid and blood replacement (see p 16). Consider early endoscopy to assess the extent of esophageal or gastric injury.
 - b. Treat hemoglobinuria resulting from hemolysis with alkaline diuresis as for rhabdomyolysis (see p 27). Treat methemoglobinemia (p 261) if it occurs.

B. Specific drugs and antidotes

1. Chelation therapy (eg, with BAL) is not effective.
2. After oral ingestion of hexavalent compounds, **ascorbic acid** has been suggested to assist the conversion of hexavalent to less toxic trivalent compounds. While no definitive studies exist, the treatment is benign and may be helpful. In animal studies the effective dose was 2–4 g of ascorbic acid orally per g of hexavalent chromium compound ingested.
3. **Acetylcysteine** (see p 405) has been used in several animal studies and one human case of dichromate poisoning.

C. Decontamination (see p 46)

1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
2. **Skin.** Remove contaminated clothing and wash exposed areas immediately with copious soap and water. EDTA (see p 440) 10% ointment may facilitate removal of chromate scabs. A 10% topical solution of ascorbic acid has been advocated to enhance the conversion of hexavalent chromium to the less toxic trivalent state.
3. **Eyes.** Irrigate copiously with tepid water or saline and perform fluorescein examination to rule out corneal injury if pain or irritation persists.
4. **Ingestion**

- a. **Prehospital.** Give milk or water to dilute corrosive effects. Do **not** induce vomiting owing to the potential for corrosive injury.
 - b. **Hospital.** Perform gastric lavage. Activated charcoal is of uncertain benefit in adsorbing chromium and may obscure the view if endoscopy is performed.
- D. Enhanced elimination.** There is no evidence for the efficacy of enhanced removal procedures such as dialysis or hemoperfusion.

Proctor DM et al: Is hexavalent chromium carcinogenic via ingestion? A weight-of-evidence review. *J Toxicol Environ Health A* 2002;65(10):701–746. [PMID: 12028825] (While hexavalent chromium is a recognized carcinogen by inhalation [lung cancer], the available scientific evidence does not find it carcinogenic in humans via the oral route at current US permissible drinking water concentrations [100 ppb].)

► CLONIDINE AND RELATED DRUGS

Cy Rangan, MD

Clonidine and the related centrally acting adrenergic inhibitors **guanabenz**, **guanfacine**, and **methyldopa** are commonly used for the treatment of hypertension. Clonidine has also been used to alleviate opioid and nicotine withdrawal symptoms. Clonidine overdose may occur after ingestion of pills or ingestion of the long-acting skin patches. **Oxymetazoline** and **tetrahydrozoline** are nasal decongestants that may cause toxicity identical to that of clonidine. **Tizanidine** is a chemically related agent used for the treatment of muscle spasticity. **Apraclonidine** and **brimonidine**, ophthalmic preparations for treatment of glaucoma and ocular hypertension, may cause poisoning from ingestion and from systemic absorption after topical administration.

- I. Mechanism of toxicity.** All of these agents decrease central sympathetic outflow by stimulating alpha-2 adrenergic presynaptic (inhibitory) receptors in the brain.
 - A. Clonidine, oxymetazoline, and tetrahydrozoline** may also stimulate peripheral alpha-1 receptors, resulting in vasoconstriction and transient hypertension.
 - B. Guanabenz** is structurally similar to guanethidine, a ganglionic blocker. **Guanfacine** is related closely to guanabenz and has more selective alpha-2-agonist activity than clonidine.
 - C. Methyldopa** may further decrease sympathetic outflow by metabolism to a false neurotransmitter (alpha-methylnorepinephrine) or by decreasing plasma renin activity.
 - D. Tizanidine** is structurally related to clonidine but has low affinity for alpha-1 receptors.
 - E. Pharmacokinetics.** The onset of effects is rapid (30 min) after oral administration of clonidine. Other than methyldopa, the drugs are widely distributed with large volumes of distribution (see also Table II–59).

II. Toxic dose

- A. Clonidine.** As little as one tablet of 0.1-mg clonidine has produced toxic effects in children; however, 10 mg shared by twin 34-month-old girls was not lethal. Adults have survived acute ingestions with as much as 100 mg. No fatalities from acute overdoses have been reported, but a child had permanent neurological damage following a respiratory arrest.
- B. Guanabenz.** Mild toxicity developed in adults who ingested 160–320 mg and in a 3-year-old who ingested 12 mg. Severe toxicity developed in a 19-month-old who ingested 28 mg. A 3-year-old child had moderate symptoms after ingesting 480 mg. All these children had recovered by 24 hours.
- C. Guanfacine.** Severe toxicity developed in a 25-year-old woman who ingested 60 mg. A 2-year-old boy ingested 4 mg and became lethargic within 20 minutes, but the peak hypotensive effect occurred 20 hours later.

- D. Methyldopa.** More than 2 g in adults is considered a toxic dose, and death was reported in an adult after an ingestion of 25 g. However, survival was reported after ingestion of 45 g. The therapeutic dose of methyldopa for children is 10–65 mg/kg/day, and the higher dose is expected to cause mild symptoms.
- E. Brimonidine.** Recurrent episodes of unresponsiveness, hypotension, hypotonia, hypothermia, and bradycardia occurred in a 1-month-old infant receiving therapeutic dosing. A 2-week-old infant had severe respiratory depression after one drop was instilled into each eye. Both children recovered with supportive care in less than 24 hours.
- III. Clinical presentation.** Manifestations of intoxication result from generalized sympathetic depression and include pupillary constriction, lethargy, coma, apnea, bradycardia, hypotension, and hypothermia. Paradoxical hypertension, caused by stimulation of peripheral alpha-1 receptors, may occur with clonidine, oxymetazoline, and tetrahydrozoline (and possibly guanabenz) and is usually transient. The onset of symptoms is usually within 30–60 minutes, although peak effects may occur more than 6–12 hours after ingestion. Full recovery is usual within 24 hours. In an unusual massive overdose, a 28-year-old man who accidentally ingested 100 mg of clonidine powder had a three-phase intoxication over 4 days: initial hypertension, followed by hypotension, and then a withdrawal reaction with hypertension.
- IV. Diagnosis.** Poisoning should be suspected in patients with pinpoint pupils, respiratory depression, hypotension, and bradycardia. Although clonidine overdose may mimic an opioid overdose, it does not usually respond to administration of naloxone.
- A. Specific levels.** Serum drug levels are not routinely available or clinically useful. These drugs are not usually detectable on comprehensive urine toxicology screening.
- B. Other useful laboratory studies** include electrolytes, glucose, and arterial blood gases or oximetry.
- V. Treatment.** Patients usually recover within 24 hours with supportive care.
- A. Emergency and supportive measures**
1. Protect the airway and assist ventilation if necessary (see pp 1–7).
 2. Treat coma (see p 19), hypotension (p 16), and bradycardia (p 10) if they occur. These usually resolve with supportive measures such as fluids, atropine, and dopamine. Hypertension is usually transient and does not require treatment.
- B. Specific drugs and antidotes**
1. **Naloxone** (see p 469) has been reported to reverse signs and symptoms of clonidine overdose, but this has not been confirmed. However, because the overdose mimics opioid intoxication, naloxone is indicated because of the possibility that narcotics may also have been ingested.
 2. Tolazoline, a central alpha-2-receptor antagonist, was previously recommended but the response has been highly variable and it should **not** be used.
- C. Decontamination** (see p 46)
1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting because of the risk of abrupt onset of obtundation and altered blood pressure.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. Enhanced elimination.** There is no evidence that enhanced removal procedures are effective.

Berlin RJ et al: Ophthalmic drops causing coma in an infant. *J Pediatr* 2001;138(3):441–443. [PMID: 11241061] (Case report of recurrent episodes of unresponsiveness, hypotension, and hypotonia due to brimonidine.)

Tessa C et al: Permanent brain damage following acute clonidine poisoning in Munchausen by proxy. *Neuropediatrics* 2001;32(2):90–92. [PMID: 11414649] (Case report of a child who had a

respiratory arrest and hypoxic encephalopathy after intentional administration of clonidine by his mother.)

► COCAINE

Neal L. Benowitz, MD

Cocaine is one of the most popular drugs of abuse. It may be sniffed into the nose (snorted), smoked, or injected intravenously. Occasionally it is combined with heroin and injected (speedball). Cocaine purchased on the street is usually of high purity, but it may occasionally contain substitute drugs such as lidocaine (see p 74) or stimulants such as caffeine (p 142), methamphetamine (p 72), ephedrine (p 320), or phencyclidine (p 300).

The “**free base**” form of cocaine is preferred for smoking because it volatilizes at a lower temperature and is not as easily destroyed by heat as the crystalline hydrochloride salt. Free base is made by dissolving cocaine salt in an aqueous alkaline solution and then extracting the free base form with a solvent such as ether. Heat is sometimes applied to hasten solvent evaporation, creating a fire hazard. “**Crack**” is a free base form of cocaine produced by using sodium bicarbonate to create the alkaline aqueous solution, which is then dried.

- I. **Mechanism of toxicity.** The primary actions of cocaine are local anesthetic effects (see p 74), CNS stimulation, and inhibition of neuronal uptake of catecholamines.
 - A. CNS stimulation and inhibition of catecholamine uptake result in a state of generalized sympathetic stimulation very similar to that of amphetamine intoxication (see p 72).
 - B. Cardiovascular effects of high doses of cocaine, presumably related to blockade of cardiac-cell sodium channels, include depression of conduction and contractility.
 - C. **Pharmacokinetics.** Cocaine is well absorbed from all routes, and toxicity has been described after mucosal application as a local anesthetic. Smoking and intravenous injection produce maximum effects within 1–2 minutes, while oral or mucosal absorption may take up to 20–30 minutes. Once absorbed, cocaine is eliminated by metabolism and hydrolysis with a half-life of about 60 minutes. In the presence of ethanol, cocaine is transesterified to **cocaethyle**, which has similar pharmacologic effects and a longer half-life than cocaine. (See also Table II–59.)
- II. **Toxic dose.** The toxic dose is highly variable and depends on individual tolerance, the route of administration, and the presence of other drugs, as well as other factors. Rapid intravenous injection or smoking may produce transient high brain and heart levels, resulting in convulsions or cardiac arrhythmias, whereas the same dose swallowed or snorted may produce only euphoria.
 - A. The usual maximum recommended dose for intranasal local anesthesia is 100–200 mg (1–2 mL of 10% solution).
 - B. A typical “line” of cocaine to be snorted contains 20–30 mg or more. Crack is usually sold in pellets or “rocks” containing 100–150 mg.
 - C. Ingestion of 1 g or more of cocaine is very likely to be fatal.
- III. **Clinical presentation**
 - A. **CNS manifestations** of toxicity may occur within minutes after smoking or intravenous injection or may be delayed for 30–60 minutes after snorting, mucosal application, or oral ingestion.
 1. Initial euphoria may be followed by anxiety, agitation, delirium, psychosis, tremulousness, muscle rigidity or hyperactivity, and seizures. High doses may cause respiratory arrest.
 2. Seizures are usually brief and self-limited; status epilepticus should suggest continued drug absorption (as from ruptured cocaine-filled condoms in the gastrointestinal tract) or hyperthermia.

3. Coma may be caused by a postictal state, hyperthermia, or intracranial hemorrhage resulting from cocaine-induced hypertension.
4. With chronic cocaine use, insomnia, weight loss, and paranoid psychosis may occur. A "washed-out" syndrome has been observed in cocaine abusers after a prolonged binge, consisting of profound lethargy and deep sleep that may last for several hours to days, followed by spontaneous recovery.
- B. **Cardiovascular toxicity** may also occur rapidly after smoking or intravenous injection and is mediated by sympathetic overactivity.
 1. Fatal ventricular tachycardia or fibrillation may occur.
 2. Severe hypertension may cause hemorrhagic stroke or aortic dissection.
 3. Coronary artery spasm and/or thrombosis may result in myocardial infarction, even in patients with no coronary disease. Diffuse myocardial necrosis similar to catecholamine myocarditis and chronic cardiomyopathy have been described.
 4. Shock may be caused by myocardial, intestinal, or brain infarction, hyperthermia, tachyarrhythmias, or hypovolemia produced by extravascular fluid sequestration owing to vasoconstriction.
 5. Renal failure may result from shock, renal arterial spasm, or rhabdomyolysis with myoglobinuria.
- C. **Death** is usually caused by a sudden fatal arrhythmia, status epilepticus, intracranial hemorrhage, or hyperthermia. Hyperthermia is usually caused by seizures, muscular hyperactivity, or rigidity and is typically associated with rhabdomyolysis, myoglobinuric renal failure, coagulopathy, and multiple organ failure.
- D. A variety of **other effects** have occurred after smoking or snorting cocaine.
 1. Chest pain without ECG evidence of myocardial ischemia is common. The presumed basis is musculoskeletal and may be associated with chest wall muscle rhabdomyolysis.
 2. Pneumothorax and pneumomediastinum cause pleuritic chest pain, and the latter is often recognized by a "crunching" sound ("Hammond's crunch") heard over the anterior chest.
 3. Nasal septal perforation may occur after chronic snorting.
 4. Accidental subcutaneous injection of cocaine may cause localized necrotic ulcers ("coke burns"), and wound botulism (see p 136) has been reported.
- E. **Body "packers" or "stuffers."** Persons attempting to smuggle cocaine may swallow large numbers of tightly packed cocaine-filled condoms ("body packers"). Street vendors suddenly surprised by a police raid may quickly swallow their wares, often without carefully wrapping or closing the packets or vials ("body stuffers"). The swallowed condoms, packets, or vials may break open, releasing massive quantities of cocaine. The packages are sometimes, but not always, visible on plain abdominal x-ray.
- IV. **Diagnosis** is based on a history of cocaine use or typical features of sympathomimetic intoxication. Skin marks of chronic intravenous drug abuse, especially with scarring from coke burns, and nasal septal perforation after chronic snorting suggest cocaine use. Chest pain with electrocardiographic evidence of ischemia or infarction in a young, otherwise healthy person also suggests cocaine use. Note that young adults, particularly young African-American men, have a high prevalence of normal J-point elevation on ECG, which can be mistaken for acute myocardial infarction.
 - A. **Specific levels.** Blood cocaine levels are not routinely available and do not assist in emergency management. Cocaine and its metabolite benzoylecgonine are easily detected in the urine and provide qualitative confirmation of cocaine use.
 - B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, CPK, urinalysis, urine myoglobin, ECG and ECG monitoring, CT head scan (if hemorrhage is suspected), and abdominal x-ray (if cocaine-filled condom or packet ingestion is suspected).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), agitation (p 24), seizures (p 22), hyperthermia (p 21), arrhythmias (pp 10–15), and hypotension (p 16) if they occur.
3. Angina pectoris may be treated with nitrates or calcium channel blockers. For acute myocardial infarction, thrombolysis has been recommended but is controversial. Supporting its use is the high prevalence of acute thrombosis, often superimposed on coronary spasm. Against its use are the excellent prognosis for patients with cocaine-induced infarction, even without thrombolysis, and concerns about increased risks of bleeding caused by intracranial hemorrhage or aortic dissection.
4. Monitor vital signs and ECG for several hours. Patients with suspected coronary artery spasm should be admitted to a coronary care unit, and because of reports of persistent or recurrent coronary spasm up to several days after initial exposure, consider use of an oral calcium antagonist and/or cardiac nitrates for 2–4 weeks after discharge.

B. Specific drugs and antidotes. There is no specific antidote. Although propranolol was previously recommended as the drug of choice for treatment of cocaine-induced hypertension, it may in fact produce paradoxical worsening of hypertension because of blockade of beta-2-mediated vasodilation; **propranolol** (see p 496) or **esmolol** (p 443) may be used **in combination** with a vasodilator such as **phenolamine** (p 487). Cardioselective beta-blockers may be used alone for treatment of tachyarrhythmias.

C. Decontamination (see p 46). Decontamination is not necessary after smoking, snorting, or intravenous injection. After **ingestion**, perform the following steps:

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
3. For ingestion of cocaine-filled condoms or packets, give repeated doses of activated charcoal and consider whole-bowel irrigation (see p 52). If large ingested packets (ie, Ziploc™ bags) are not removed by these procedures, laparotomy and surgical removal may be necessary.

D. Enhanced elimination. Because cocaine is extensively distributed to tissues and rapidly metabolized, dialysis and hemoperfusion procedures are not effective. Acidification of the urine does not significantly enhance cocaine elimination and may aggravate myoglobinuric renal failure.

Bauman JL, DiDomenico RJ: Cocaine-induced channelopathies: emerging evidence on the multiple mechanisms of sudden death. *J Cardiovasc Pharmacol Ther* 2002;7(3):195–202. [PMID: 12232568] (Cocaine at high doses has sodium channel blocking effects and can prolong the QRS interval; at lower doses it may block potassium channels, prolonging the QT interval and causing sudden death due to torsade de pointes.)

Furnari C et al: A fatal case of cocaine poisoning in a body packer. *J Forensic Sci* 2002;47(1):208–210. [PMID: 12064655] (A 27-year-old man carrying 99 packages containing about 10 g of 86% cocaine powder died after four of the packages ruptured during a transatlantic flight.)

► COLCHICINE

Yao-ming Hung, MD

Colchicine is marketed in tablets used for treatment of gout and familial Mediterranean fever and is found in certain plants: autumn crocus or meadow saffron (*Colchicum autumnale*) and glory lily (*Gloriosa superba*). A colchicine overdose is ex-

tremely serious, with considerable mortality that is often delayed. Colchicine has been used as a homicidal poison.

- I. **Mechanism of toxicity.** Colchicine inhibits mitosis of dividing cells and, in high concentrations, is a general cellular poison. Colchicine is rapidly absorbed and extensively distributed to body tissues (volume of distribution 2–20 L/kg). (See also Table II–59.)
- II. **Toxic dose.** The maximum therapeutic dose of colchicine is 8–10 mg in 1 day. Tablets contain 0.5–0.6 mg. Fatalities have been reported with single ingestions of as little as 7 mg, although another case report described survival after alleged ingestion of more than 60 mg. In a series of 150 cases, doses of 0.5 mg/kg were associated with diarrhea and vomiting but not death; 0.5–0.8 mg/kg with marrow aplasia and 10% mortality. Ingestions of parts of colchicine-containing plants have resulted in severe toxicity and death.
- III. **Clinical presentation.** Colchicine poisoning affects many organ systems, with toxic effects occurring over days to weeks.
 - A. After an **acute overdose**, symptoms are typically delayed for 2–12 hours and include nausea, vomiting, abdominal pain, and severe bloody diarrhea. Shock results from depressed cardiac contractility and fluid loss into the gastrointestinal tract and other tissues. Delirium, seizures, or coma may occur. Lactic acidosis related to shock and inhibition of cellular metabolism is common. Other manifestations of acute colchicine poisoning include acute myocardial injury, rhabdomyolysis with myoglobinuria, disseminated intravascular coagulation, and acute renal failure.
 - B. **Death** usually occurs after 8–36 hours and is caused by respiratory failure, intractable shock, and cardiac arrhythmias or sudden cardiac arrest.
 - C. **Late complications** include bone marrow suppression, particularly leukopenia and thrombocytopenia (4–5 days) and alopecia (2–3 weeks). Chronic colchicine therapy may produce myopathy (proximal muscle weakness and elevated creatinine kinase levels) and polyneuropathy. This has also occurred after acute poisoning.
- IV. **Diagnosis.** A syndrome beginning with severe gastroenteritis, leucocytosis, shock, rhabdomyolysis, and acute renal failure and, several days later, leukopenia and thrombocytopenia should suggest colchicine poisoning. A history of gout or familial Mediterranean fever in the patient or a family member is also suggestive.
 - A. **Specific levels.** Colchicine levels in blood and urine are not readily available. However, levels may be useful for forensic purposes, especially in cases of unexplained pancytopenia and multiple organ failure. Bone marrow biopsy may reveal metaphase arrest and “pseudo-Pelger-Huet” cells.
 - B. **Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, CPK, troponin I, urinalysis, and ECG monitoring. Elevated serum levels of troponin I (TnI), a highly specific marker of myocardial injury, suggest greater severity of myocardial necrosis and higher mortality.
- V. **Treatment**
 - A. **Emergency and supportive measures.** Provide aggressive supportive care, with careful monitoring and treatment of fluid and electrolyte disturbances.
 1. Anticipate sudden respiratory or cardiac arrest, and maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treatment of shock (see p 16) may require large amounts of crystalloid fluids, possibly blood (to replace loss from hemorrhagic gastroenteritis), and pressor agents such as dopamine (p 438).
 3. Infusion of sodium bicarbonate and mannitol is recommended if there is evidence of rhabdomyolysis (see p 27).
 4. Bone marrow depression requires specialized intensive care. Severe neutropenia requires patient isolation and management of febrile episodes as for other neutropenic conditions. Platelet transfusions may be required to control bleeding.
 - B. **Specific drugs and antidotes.** Colchicine-specific antibodies (Fab fragments) were used successfully in France to treat a 25-year-old woman with

severe colchicine overdose. Unfortunately, they have never been available in the United States, and it is not certain if they will be produced commercially in Europe. Granulocyte colony-stimulating factor (G-CSF) has been used for the treatment of severe leukopenia.

C. Decontamination (see p 47)

1. Prehospital. Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of the exposure.

2. Hospital. Administer activated charcoal. Consider gastric lavage for large ingestions.

D. Enhanced elimination. Because colchicine is highly bound to tissues, with a large volume of distribution, hemodialysis and hemoperfusion are ineffective. Colchicine undergoes enterohepatic recirculation, so **repeat-dose charcoal** might be expected to accelerate elimination, although this has not been documented.

Maxwell MJ et al: Accidental colchicine overdose. A case report and literature review. *Emerg Med J* 2002;19(3):265–267. [PMID: 11971849] (A fatal case of colchicine poisoning caused by inappropriate self-medication; clinical features and options for treatment are discussed.)

► COPPER

Alan Buchwald, MD

Copper is widely used in its elemental metallic form, in metal alloys, and in the form of copper salts. Elemental metallic copper is used in electrical wiring and plumbing materials and was formerly the main constituent of pennies (now mostly zinc). Copper salts such as copper sulfate, copper oxide, copper chloride, copper nitrate, copper cyanide, and copper acetate are used as pesticides and algicides and in a variety of industrial processes. Because of its toxicity, copper sulfate is no longer used as an emetic. Copper levels may be elevated in persons drinking from copper containers or using copper plumbing. The increased acidity of beverages stored in copper alloy (eg, brass or bronze) containers enhances leaching of copper into the liquid.

I. Mechanism of toxicity

A. Elemental metallic copper is poorly absorbed orally and is essentially non-toxic. However, inhalation of copper dust, or metallic fumes created when welding or brazing copper alloys may cause chemical pneumonitis or a syndrome similar to metal fume fever (see p 259). Metallic copper dust in the eye (chalcosis) may lead to corneal opacification, uveitis, ocular necrosis, and blindness unless the dust is removed quickly.

B. Copper sulfate salt is highly irritating, depending on the concentration, and may produce mucous membrane irritation and severe gastroenteritis.

C. Systemic absorption can produce hepatic and renal tubular injury. Hemolysis has been associated with copper exposure from hemodialysis equipment or absorption through burned skin.

II. Toxic dose. Copper is an essential trace metal. The daily adult requirement of 2 mg is supplied in a normal diet.

A. Inhalation. The recommended workplace limit (ACGIH TLV-TWA) for copper fumes is 0.2 mg/m³; for dusts and mists, it is 1 mg/m³. The air level considered immediately dangerous to life or health for dusts or fumes is 100 mg Cu/m³.

B. Ingestion of more than 250 mg of copper sulfate can produce vomiting, and larger ingestions can potentially cause hepatic and renal injury.

C. Water. The US Environmental Protection Agency (EPA) has established a safe limit of 1.3 mg/L in drinking water.

III. Clinical presentation

- A. Inhalation of copper fumes or dusts** initially produces a metallic taste and upper respiratory irritation (dry cough, sore throat, and eye irritation). Large exposures may cause severe cough, dyspnea, fever, leukocytosis, and pulmonary infiltrates (see also metal fume fever, p 259).
- B. Ingestion of copper sulfate or other salts** causes the rapid onset of nausea and vomiting with characteristic blue-green emesis. Gastrointestinal bleeding may occur. Fluid and blood loss from gastroenteritis may lead to hypotension and oliguria. Intravascular hemolysis can result in acute tubular necrosis. Hepatitis has been reported, due to centrilobular necrosis. Multisystem failure, shock, and death may occur. Chronic interstitial nephritis has been reported after parenteral copper sulfate poisoning.
- C. Chronic** exposure to Bordeaux mixture (copper sulfate with hydrated lime) may occur in vineyard workers. Pulmonary fibrosis, lung cancer, cirrhosis, angiosarcoma, and portal hypertension have been associated with this occupational exposure.
- D.** Swimming in water contaminated with copper-based algicides can cause green discoloration of the hair.

IV. Diagnosis is based on a history of acute ingestion or occupational exposure. Occupations at risk include those associated with handling algicides, herbicides, wood preservatives, pyrotechnics, ceramic glazes, electrical wiring, and welding or brazing copper alloys.

- A. Specific levels.** If copper salt ingestion is suspected, a serum copper level should be obtained. Normal serum copper concentrations average 1 mg/L, and this doubles during pregnancy. Serum copper levels above 5 mg/L are considered very toxic. Whole-blood copper levels may correlate better with acute intoxication because acute excess copper is carried in the red blood cells; however, whole-blood copper levels are not as widely available.
- B. Other useful laboratory studies** include CBC, electrolytes, BUN, creatinine, hepatic transaminases, arterial blood gases or oximetry, and chest x-ray. If hemolysis is suspected, send blood for type and cross-match, plasma free hemoglobin, and haptoglobin, and check urinalysis for occult blood (hemoglobinuria).

V. Treatment

A. Emergency and supportive measures

- 1. Inhalation of copper fumes or dusts.** Give supplemental oxygen if indicated by arterial blood gases or oximetry, and treat bronchospasm (see p 8) and chemical pneumonitis (p 7) if they occur. Symptoms are usually short-lived and resolve without specific treatment.
- 2. Ingestion of copper salts**
 - a.** Treat shock caused by gastroenteritis with aggressive intravenous fluid replacement and, if necessary, pressor drugs (see p 16).
 - b.** Consider endoscopy to rule out corrosive esophageal or stomach injury, depending on the concentration of the solution and the patient's symptoms.
 - c.** Blood transfusion may be needed if significant hemolysis or gastrointestinal bleeding occurs.

B. Specific drugs and antidotes. **BAL** (dimercaprol; see p 413) and **penicillamine** (see p 484) are effective chelating agents and should be used in seriously ill patients with large ingestions. Triethyl tetramine dihydrochloride (Trien or Cuprid) is a specific copper chelator approved for use in Wilson's disease; although it is better tolerated than penicillamine, its role in acute ingestion or chronic environmental exposure has not been established.

C. Decontamination (see p 46)

- 1. Inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
- 2. Eyes.** Irrigate copiously and attempt to remove all copper from the surface; perform a careful slit-lamp exam and refer the case to an ophthalmologist urgently if any residual material remains.

3. Ingestion

a. **Prehospital.** Do **not** induce vomiting because it may worsen gastroenteritis.

b. **Hospital.** Perform gastric lavage if there has been a recent ingestion of a large quantity of copper salts. There is no proven benefit for activated charcoal, and its use may obscure the view if endoscopy is performed.

D. **Enhanced elimination.** There is no role for hemodialysis, hemoperfusion, repeat-dose charcoal, hemodiafiltration, or other enhanced elimination techniques. Hemodialysis may be required for supportive care of patients with acute renal failure, and it can marginally increase the elimination of the copper-chelator complex.

Liu J et al: Death following cupric sulfate emesis. *J Toxicol Clin Toxicol* 2001;39(2):161–163. [PMID: 11407502] (Case report of fatal copper poisoning after it was used inappropriately as an emetic or a patient with a diazepam overdose. The patient developed hemolysis and acute renal failure. Postmortem blood Cu level was 5.31 mg/L.)

► CYANIDE

Paul D. Blanc, MD, MSPH

Cyanide is a highly toxic chemical with a variety of uses, including chemical synthesis, laboratory analysis, and metal plating. Aliphatic nitriles (acrylonitrile and propionitrile) used in plastics manufacturing are metabolized to cyanide. The vasodilator drug nitroprusside releases cyanide on exposure to light or through metabolism. Natural sources of cyanide (amygdalin and many other cyanogenic glycosides) are found in apricot pits, cassava, and many other plants and seeds, some of which may be important depending on ethnobotanical practices. Acetonitrile, a component of some artificial nail glue removers, has caused several pediatric deaths.

Hydrogen cyanide is a gas easily generated by mixing acid with cyanide salts and is a common combustion by-product of burning plastics, wool, and many other natural and synthetic products. Hydrogen cyanide poisoning is an important cause of death from structural fires, and deliberate cyanide exposure remains an important instrument of homicide and suicide.

I. **Mechanism of toxicity.** Cyanide is a chemical asphyxiant; binding to cellular cytochrome oxidase, it blocks the aerobic utilization of oxygen. Unbound cyanide is detoxified by metabolism to thiocyanate, a much less toxic compound that is excreted in the urine.

II. Toxic dose

A. Exposure to **hydrogen cyanide gas** (HCN) even at low levels (150–200 ppm) can be fatal. The air level considered immediately dangerous to life or health (IDLH) is 50 ppm. The recommended workplace ceiling limit (ACGIH TLV-C) for HCN is 4.7 ppm (5 mg/m³). The OSHA permissible exposure limit (PEL) is 10 ppm. HCN is well absorbed across the skin.

B. Adult **ingestion** of as little as 200 mg of the sodium or potassium salt may be fatal. Solutions of cyanide salts can be absorbed through intact skin.

C. Acute cyanide poisoning is relatively rare with nitroprusside infusion (at normal infusion rates) or after ingestion of amygdalin-containing seeds (unless they have been pulverized).

III. **Clinical presentation.** Abrupt onset of profound toxic effects shortly after exposure is the hallmark of cyanide poisoning. Symptoms include headache, nausea, dyspnea, and confusion. Syncope, seizures, coma, agonal respirations, and cardiovascular collapse ensue rapidly after heavy exposure.

A. Brief delay may occur if the cyanide is ingested as a salt, especially if it is in a capsule or if there is food in the stomach.

- B. Delayed onset (minutes to hours) may also occur after ingestion of nitriles and plant-derived cyanogenic glycosides, because metabolism to cyanide is required.
 - C. Chronic neurologic sequelae may follow severe cyanide poisoning.
- IV. **Diagnosis** is based on a history of exposure or the presence of rapidly progressive symptoms and signs. Severe lactic acidosis is usually present with significant exposure. The **measured venous oxygen saturation** may be elevated owing to blocked cellular oxygen consumption. The classic “bitter almond” odor of hydrogen cyanide may or may not be noted, because of genetic variability in the ability to detect the smell.
- A. **Specific levels.** Cyanide determinations are rarely of use in emergency management because they cannot be performed rapidly enough to influence initial treatment. In addition, they must be interpreted with caution because of a variety of complicating technical factors.
 - 1. Whole-blood levels higher than 0.5–1 mg/L are considered toxic.
 - 2. Cigarette smokers may have levels up to 0.1 mg/L.
 - 3. Rapid nitroprusside infusion may produce levels as high as 1 mg/L, accompanied by metabolic acidosis.
 - B. **Other useful laboratory studies** include electrolytes, glucose, serum lactate, arterial blood gas, mixed venous oxygen saturation, and carboxyhemoglobin (if patient had a smoke inhalation exposure).
- V. **Treatment**
- A. **Emergency and supportive measures.** Treat all cyanide exposures as potentially lethal.
 - 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 - 2. Treat coma (see p 19), hypotension (p 16), and seizures (p 22) if they occur.
 - 3. Start an intravenous line and monitor the patient’s vital signs and ECG closely.
 - B. **Specific drugs and antidotes**
 - 1. The **cyanide antidote package** (Taylor Pharmaceuticals) consists of amyl and sodium **nitrites** (see p 476), which produce cyanide-scavenging methemoglobinemia, and sodium **thiosulfate** (p 505), which accelerates the conversion of cyanide to thiocyanate.
 - a. Break a pearl of **amyl nitrite** under the nose of the victim; and administer **sodium nitrite**, 300 mg IV (6 mg/kg for children, not to exceed 300 mg). Adjust the dose downward if anemia is present (see p 476). **Caution:** Nitrite-induced methemoglobinemia can be extremely dangerous and even lethal. Nitrite should not be given if the symptoms are mild or if the diagnosis is uncertain, especially if concomitant carbon monoxide poisoning is suspected.
 - b. Administer **sodium thiosulfate**, 12.5 g IV. Thiosulfate is relatively benign and may be given empirically even if the diagnosis is uncertain. It may also be useful in mitigating nitroprusside toxicity (see p 505).
 - 2. The most promising alternative antidote is **hydroxocobalamin** (see p 453). Unfortunately, it remains an investigational drug in the United States.
 - 3. **Hyperbaric oxygen** has no proven role in cyanide poisoning treatment.
 - C. **Decontamination** (see p 46). **Caution:** Avoid contact with cyanide-containing salts or solutions, and avoid inhaling vapors from vomitus (which may give off hydrogen cyanide gas).
 - 1. **Inhalation.** Remove victims from hydrogen cyanide exposure and give supplemental oxygen if available. Each rescuer should wear a positive-pressure, self-contained breathing apparatus and, if possible, chemical-protective clothing.
 - 2. **Skin.** Remove and isolate all contaminated clothing and wash affected areas with copious soap and water.

3. **Ingestion** (see p 47). Even though charcoal has a relatively low affinity for cyanide, it will effectively bind the doses typically ingested (eg, 100–500 mg).
 - a. **Prehospital.** Immediately administer activated charcoal if available. Do **not** induce vomiting unless victim is more than 20 minutes from a medical facility and charcoal is not available.
 - b. **Hospital.** Immediately place a gastric tube and administer activated charcoal, then perform gastric lavage. Give additional activated charcoal and a cathartic after the lavage.
- D. **Enhanced elimination.** There is no role for hemodialysis or hemoperfusion in cyanide poisoning treatment. Hemodialysis may be indicated in patients with renal insufficiency who develop high thiocyanate levels while on extended nitroprusside therapy.

Baud FJ et al: Value of lactic acidosis in the assessment of the severity of acute cyanide poisoning. *Crit Care Med* 2002;30(9):2044–2050. [PMID: 12352039] (Ten-year retrospective analysis of 11 patients with CN poisoning. The median plasma lactate concentration was 168 mg/dL before antidotal therapy.)

Beasley DM, Glass WI: Cyanide poisoning: pathophysiology and treatment recommendations. *Occup Med (Lond)* 1998;48(7):427–431. [PMID: 10024740] (Review of the mechanism of toxicity of cyanide and the rationale for treatment options.)

► DAPSONE

Kathryn H. Meier, PharmD

Dapsone is an antibiotic used to treat leprosy and for prophylaxis against malaria and *Pneumocystis carinii* infections in patients with AIDS and other immunodeficiency disorders. It is also used in rheumatologic and rare dermatologic disorders.

- I. **Mechanism of toxicity.** Toxic effects are caused by the P-450 metabolites and include methemoglobinemia, sulfhemoglobinemia, and Heinz-body hemolytic anemia—all of which decrease the oxygen-carrying capacity of the blood.
 - A. Dapsone metabolites oxidize the ferrous iron hemoglobin complex to the ferric state, resulting in methemoglobinemia.
 - B. Sulfhemoglobinemia occurs when dapsone metabolites sulfate the pyrrole hemoglobin ring; this is an irreversible reaction, and there is no antidote.
 - C. Hemolysis may occur owing to depletion of intracellular glutathione by oxidative metabolites.
- D. **Pharmacokinetics.** Absorption of dapsone is delayed; peak plasma levels occur between 4 and 8 hours after ingestion. The volume of distribution (Vd) is 1.5 L/kg. Protein binding is approximately 70–90%. Dapsone is metabolized by two primary routes, acetylation and P-450 oxidation. Both dapsone and its acetylated metabolite undergo enterohepatic recirculation. The average elimination half-life is 30 hours after a therapeutic dose and as long as 77 hours after an overdose. (See also Table II–59.)
- II. **Toxic dose.** The adult therapeutic dose ranges from 50 to 300 mg/day. Chronic daily dosing of 100 mg has resulted in methemoglobin levels of 5–12%. Hemolysis has not been reported in adults with doses less than 300 mg/day. Persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency, congenital hemoglobin abnormalities, or underlying hypoxemia may experience greater toxicity at lower doses. Death has occurred with overdoses of 1.4 g and greater, although recovery from severe toxicity has been reported after ingestion of 7.5 g.
- III. **Clinical presentation** includes methemoglobinemia, sulfhemoglobinemia, and intravascular hemolysis. Clinical manifestations are more severe in patients with underlying medical conditions that may contribute to hypoxemia.
 - A. **Methemoglobinemia** (see p 261) causes cyanosis and dyspnea. Drawn blood may appear dark “chocolate” brown when the methemoglobin level is

greater than 15–20%. Because of the long half-life of dapsone and its metabolites, methemoglobinemia may persist for several days, requiring repeated antidotal treatment.

B. Sulfhemoglobinemia also decreases oxyhemoglobin saturation, and is unresponsive to methylene blue, so victims may remain cyanotic even after receiving antidotal treatment for methemoglobinemia. Even though sulfhemoglobinemia can produce a cyanotic appearance at a lower percentage of total hemoglobin compared with methemoglobin, it is not commonly diagnosed because the amount of sulfhemoglobin generated is rarely more than 5%.

C. Hemolysis. Heinz bodies may be seen, but hemolysis may be delayed in onset 2–3 days after the ingestion.

IV. Diagnosis is based on a history of dapsone use and should be suspected in any immunocompromised patient with a suspected drug overdose, particularly since manifestations of toxicity may be delayed. Although there are many agents that can cause methemoglobinemia, there are very few that produce both detectable sulfhemoglobin and a prolonged, recurrent methemoglobinemia.

A. Specific levels. Dapsone levels are not routinely available.

1. **Methemoglobinemia** (see p 261) is suspected when a cyanotic patient fails to respond to high-flow oxygen or cyanosis persists despite a normal arterial PO_2 (note that pulse oximetry is not a reliable indicator of oxygen saturation in patients with methemoglobinemia). Specific methemoglobin concentrations can be measured using a multiwave cooximeter. Qualitatively, a drop of blood on white filter paper will appear brown (when directly compared with normal blood) if the methemoglobin level is greater than 15–20%.

2. **Note:** administration of the antidote **methylene blue** (see V.B.1. below) can cause transient false elevation of the measured methemoglobin level (up to 15%).

3. **Sulfhemoglobin** is difficult to detect, in part because its spectrophotometric absorbance is similar to methemoglobin on the cooximeter. If a crystal of potassium cyanide is added to a blood sample, blood will become red, but not if significant sulfhemoglobin is present.

4. The oxygen-carrying capacity of the blood is dependent not only on oxygen saturation, but on total hemoglobin concentration. Interpret methemoglobin and sulfhemoglobin levels with reference to the degree of anemia.

B. Other useful laboratory studies include CBC (with differential smear to look for reticulocytes and Heinz bodies), glucose, electrolytes, liver transaminases, bilirubin, and arterial blood gases.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if needed (pp 1–7). Administer supplemental oxygen.

2. If hemolysis occurs, administer intravenous fluids and alkalinize the urine, as for rhabdomyolysis (see p 27), to prevent acute renal tubular necrosis. For severe hemolysis, blood transfusions may be required.

3. Mild symptoms may resolve without intervention, although it may take 2–3 days.

B. Specific drugs and antidotes

1. **Methylene blue** (see p 466) is indicated in the symptomatic patient with a methemoglobin level greater than 20% or with lower levels if even minimal compromise of oxygen-carrying capacity is potentially harmful (eg, severe pneumonia, anemia, or myocardial ischemia).

a. Give 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) over several minutes. Therapeutic response may be delayed up to 30 minutes.

b. Serious overdoses usually require repeated dosing every 6–8 hours for 2–3 days because of the prolonged half-life of dapsone and its metabolites.

- c. Methylene blue is ineffective for sulfhemoglobin, and can cause hemolysis in patients with G6PD deficiency. Excessive doses may worsen methemoglobinemia.
- 2. Other therapies such as ascorbic acid, cimetidine, and vitamin E have been proposed, but their efficacy is unproven.
- C. Decontamination** (see p 47)
 - 1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 - 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary after a small ingestion if activated charcoal can be given promptly, but it should be considered for a large overdose (eg, more than 75 mg/kg), even if it has been more than 60 minutes since the ingestion (one report documented tablet fragment return 5 hours after ingestion).
- D. Enhanced elimination** (see p 54)
 - 1. **Repeat-dose activated charcoal** interrupts enterohepatic recirculation and is very effective, reducing the half-life from 77 to 13.5 hours in one report. Continue charcoal for at least 48–72 hours. Do **not** use charcoal/sorbitol suspension (see p 57).
 - 2. **Charcoal hemoperfusion** can reduce the half-life to 1.5 hours and might be considered in a severe intoxication unresponsive to conventional treatment. Hemodialysis is ineffective because dapsone and its metabolites are highly protein bound.

Falkenhahn M et al: Unexplained acute severe methaemoglobinaemia in a young adult. *Br J Anaesth* 2001 Feb;86(2):278–280. [PMID: 11573675] (A young woman developed methemoglobinemia [47%] due to dapsone.)

MacDonald RD, McGuigan MA: Acute dapsone intoxication: a pediatric case report. *Pediatr Emerg Care* 1997;13(2):127–129. [PMID: 9127424] (Ingestion of 37.5 mg/kg by a 3-year-old resulted in a methemoglobin level of 44%. Treatment with methylene blue was successful, but methemoglobinemia recurred 64 hours after ingestion.)

► DETERGENTS

Michael J. Walsh, MD

Detergents, familiar and indispensable products in the home, are synthetic surface-active agents chemically classified as **anionic**, **nonionic**, or **cationic** (Table II–22). Most products also contain bleaching (chlorine-releasing), bacteriostatic (having a low concentration of quaternary ammonium compound), or enzymatic agents. Accidental ingestion of detergents by children is very common, but severe toxicity rarely occurs.

- 1. **Mechanism of toxicity.** Detergents may precipitate and denature protein, are irritating to tissues, and possess keratolytic and corrosive actions.

TABLE II–22. COMMON CATIONIC DETERGENTS

Pyridinium compounds	Quaternary ammonium compounds	Quinolinium compounds
Cetalkonium chloride	Benzalkonium chloride	Dequalinium chloride
Cetrimide	Benzethonium chloride	
Cetrimonium bromide		
Cetylpyridinium chloride		
Stearalkonium chloride		

- A. **Anionic** and **nonionic** detergents are only mildly irritating, but **cationic** detergents are more hazardous because quaternary ammonium compounds may be caustic (benzalkonium chloride solutions of 10% have been reported to cause corrosive burns).
- B. **Low-phosphate** detergents and **electric dishwasher** soaps often contain alkaline corrosive agents such as sodium metasilicate, sodium carbonate, and sodium tripolyphosphate.
- C. The **enzyme-containing** detergents may cause skin irritation and have sensitizing properties; they may release bradykinin and histamine, causing bronchospasm.
- II. **Toxic dose.** Mortality and serious morbidity are rare, but the nature of the toxic effect varies with the ingredients and concentration of the product. Cationic and dishwasher detergents are more dangerous than anionic and nonionic products. For benzalkonium chloride solutions, ingestion of 100–400 mg/kg has been fatal.
- III. **Clinical presentation.** Immediate spontaneous vomiting often occurs after oral ingestion. Large ingestions may produce intractable vomiting, diarrhea, and hematemesis. Corrosive injury to the lips, mouth, pharynx, and upper GI tract can occur. Exposure to the eye may cause mild to serious corrosive injury depending on the specific product. Dermal contact generally causes a mild erythema or rash.
 - A. Phosphate-containing products may produce hypocalcemia, hypomagnesemia, tetany, and respiratory failure.
 - B. Methemoglobinemia was reported in a 45-year-old woman after copious irrigation of a hydatid cyst with a 0.1% solution of cetrimide, a cationic detergent.
- IV. **Diagnosis** is based on a history of exposure and prompt onset of vomiting. A sudsy or foaming mouth may also suggest exposure.
 - A. **Specific levels.** There are no specific blood or urine levels.
 - B. **Other useful laboratory studies** include electrolytes, glucose, calcium, magnesium and phosphate (after ingestion of phosphate-containing products), and methemoglobin (cationic detergents).
- V. **Treatment**
 - A. **Emergency and supportive measures**
 - 1. In patients with protracted vomiting or diarrhea, administer intravenous fluids to correct dehydration and electrolyte imbalance (see p 16).
 - 2. If corrosive injury is suspected, consult a gastroenterologist for possible endoscopy. Ingestion of products containing greater than 5–10% cationic detergents is more likely to cause corrosive injury.
 - B. **Specific drugs and antidotes.** If symptomatic hypocalcemia occurs after ingestion of a phosphate-containing product, administer intravenous **calcium** (see p 424). If methemoglobinemia occurs, administer **methylene blue** (p 466).
 - C. **Decontamination** (see p 46)
 - 1. **Ingestion.** Dilute orally with small amounts of water or milk. A significant ingestion is unlikely if spontaneous vomiting has not already occurred.
 - a. Do **not** induce vomiting, because of the risk for corrosive injury.
 - b. Consider gentle gastric lavage using a small, flexible tube after very large ingestions of cationic, corrosive, or phosphate-containing detergents.
 - c. Activated charcoal is not effective. Oral aluminum hydroxide can potentially bind phosphate in the gastrointestinal tract.
 - 2. **Eyes and skin.** Irrigate with copious amounts of tepid water or saline. Consult an ophthalmologist if eye pain persists or if there is significant corneal injury on fluorescein examination.
 - D. **Enhanced elimination.** There is no role for these procedures.

Hitosugi M et al: A case of fatal benzalkonium chloride poisoning. *Int J Legal Med* 1998;111(5):265–266. [PMID: 9728755] (Five elderly patients with dementia accidentally ingested a 10% solution of benzalkonium chloride. One patient died with corrosive injuries to the tongue, pharynx, larynx, esophagus, and stomach.)

Vincent JC, Sheikh A: Phosphate poisoning by ingestion of clothes washing liquid and fabric conditioner. *Anaesthesia* 1998;53(10):1004–1006. [PMID: 9893545] (Deliberate ingestion of a phosphate-containing product resulted in hypocalcemia and respiratory muscle dysfunction.)

► DEXTROMETHORPHAN

Timothy E. Albertson, MD, PhD

Dextromethorphan is a common antitussive agent found in many over-the-counter cough and cold preparations. Many ingestions occur in children, but severe intoxication is rare. Dextromethorphan is often found in combination products containing antihistamines (see p 96), decongestants (p 320), ethanol (p 190), or acetaminophen (p 66). *Common combination products containing dextromethorphan* include Coricidin HBP Cough & Cold Tablets, Nyquil Nighttime Cold Medicine, Triaminic Nite Lite, Pediacare 1, Pediacare 3, Robitussin DM, Robitussin CF, Triaminic DM, and Vicks Pediatric Formula 44. A recent study of dextromethorphan ingestions noted that 71% of cases involved intentional abuse, and 85% of the abusers were 13–17 years old.

- I. **Mechanism of toxicity.** Dextromethorphan is the *d*-isomer of 3-methoxy-*N*-methylmorphinan, a synthetic analog of codeine. (The *l*-isomer is the opioid analgesic levorphanol.) Although it has approximately equal antitussive efficacy as codeine, dextromethorphan has no apparent analgesic or addictive properties and produces relatively mild opioid effects in overdose.
 - A. Both dextromethorphan and its *o*-demethylated metabolite appear to antagonize *N*-methyl-D-aspartate (NMDA) glutamate receptors, which may explain anticonvulsant properties and protection against hypoxia-ischemia observed in animal models.
 - B. Dextromethorphan inhibits reuptake of serotonin, and may lead to the **serotonin syndrome** (see p 22) in patients taking monoamine oxidase inhibitors (p 269). Serotonergic effects, as well as NMDA glutamate receptor inhibition, may explain the acute and chronic abuse potential of dextromethorphan.
 - C. Dextromethorphan hydrobromide can cause bromide poisoning (see p 140).
 - D. **Pharmacokinetics.** Dextromethorphan is well absorbed orally, and effects are often apparent within 15–30 minutes (peak 2.5 hours). The volume of distribution is approximately 5–6 L/kg. The duration of effect is normally 3–6 hours. A genetic polymorphism exists for the debrisoquin hydroxylase enzyme (P450 2D6). Dextromethorphan is a high-affinity substrate for this enzyme. Rapid metabolizers have a plasma half-life of about 3–4 hours, but in slow metabolizers (about 10% of the population) the half-life may exceed 24 hours. In addition, dextromethorphan competitively inhibits P450 2D6-mediated metabolism, leading to many potential drug interactions. (See also Table II–59.)
- II. **Toxic dose.** The toxic dose is highly variable and depends largely on other ingredients in the ingested product. Symptoms usually occur when the amount of dextromethorphan ingested exceeds 10 mg/kg. The usual recommended adult daily dose of dextromethorphan is 60–120 mg/day; in children age 2–5 years, up to 30 mg/day.
- III. **Clinical presentation**
 - A. **Mild intoxication** produces clumsiness, dizziness, ataxia, nystagmus, mydriasis, and restlessness. Visual and auditory hallucinations have been reported.
 - B. With **severe poisoning**, stupor, coma, and respiratory depression may occur, especially if alcohol has been co-ingested. The pupils may be constricted or dilated. A few cases of seizures have been reported after ingestions of more than 20–30 mg/kg.
 - C. **Serotonin syndrome** (see p 22). Severe hyperthermia, muscle rigidity, and hypertension may occur with therapeutic doses in patients taking **monoamine oxidase inhibitors** (p 269).

IV. Diagnosis should be considered with ingestion of any over-the-counter cough suppressant, especially when there is nystagmus, ataxia, and lethargy. Because dextromethorphan is often combined with other ingredients (eg, antihistamines, phenylpropanolamine, or acetaminophen), suspect mixed ingestion.

- A. Specific levels.** Assays exist for serum and urine analysis, but are not generally available. In seven fatal infant cases, blood levels averaged 0.38 mg/L (range 0.10–0.95). Despite its structural similarity to opioids, dextromethorphan is not likely to produce a false-positive urine opioid immunoassay screen. However, it may produce a false-positive result on methadone and phencyclidine immunoassays. Dextromethorphan is readily detected by comprehensive urine toxicology screening.
- B. Other useful laboratory studies** include electrolytes, glucose, and arterial blood gases (if respiratory depression is suspected). Blood ethanol and acetaminophen levels should be obtained if those drugs are contained in the ingested product.

V. Treatment

- A. Emergency and supportive measures.** Most patients with mild symptoms (ie, restlessness, ataxia, or mild drowsiness) can be observed for 4–6 hours and discharged if they are improving.
 1. Maintain an open airway and assist ventilation if needed (see pp 1–7).
 2. Treat seizures (see p 22) and coma (p 19) if they occur.
- B. Specific drugs and antidotes.** Although **naloxone** (see p 469) has been reported effective in doses of 0.06–0.4 mg, other cases have failed to respond to doses up to 2.4 mg.
- C. Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because signs of intoxication can develop rapidly.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. Enhanced elimination.** The volume of distribution of dextromethorphan is very large, and there is no role for enhanced removal procedures.

Banerji S, Anderson IB: Abuse of Coricidin HBP cough & cold tablets: episodes recorded by a poison center. *Am J Health Syst Pharm* 2001;58(19):1811–1814. [PMID: 11596695] (Report documents high rate of abuse of Coricidin HBP among teenagers.)

Roberge RJ et al: Dextromethorphan- and pseudoephedrine-induced agitated psychosis and ataxia: case report. *J Emerg Med* 1999;17(2):285–288. [PMID: 10195488] (A 2-year-old developed irritability, psychosis, and ataxia after being overmedicated with a combination OTC cough preparation.)

► DIOXINS

Stephen C. Born, MD, MPH

Polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs) are a group of highly toxic substances commonly known as dioxins. Dioxins are not commercially produced. PCDDs are formed during the production of certain organochlorines (trichlorophenoxyacetic acid [2,4,5-T], Silvex, hexachlorophene, pentachlorophenol, etc), and PCDDs and PCDFs are formed by the combustion of these and other compounds such as polychlorinated biphenyls (PCBs; see p 319). Agent Orange, a herbicide used by the United States against Vietnam during the Vietnam War, contained dioxins (most importantly, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [TCDD]) as contaminants. Some PCBs have biological activity similar to dioxins and are identified as “dioxin-like.”

- I. Mechanism of toxicity.** Dioxins are highly lipid soluble and are concentrated in fat and the thymus. Dioxins are known to induce porphyrinogen synthesis and oxidative cytochrome P-450 metabolism and have a variety of effects on various

organ systems. The actual mechanism of toxicity is unknown. They are mutagenic and are suspected human carcinogens. TCDD is one of the most potent animal carcinogens known and is considered a human carcinogen by both the EPA and IARC.

- II. Toxic dose.** Dioxins are extremely potent animal toxins. The FDA-suggested “no effect” level for inhalation is 70 ng/day per person. The oral 50% lethal dose (LD_{50}) in animals varies from 0.0006 to 0.045 mg/kg. Daily dermal exposure to 10–30 ppm in oil or 100–3000 ppm in soil produces toxicity in animals. Chloracne is likely with daily dermal exposure exceeding 100 ppm. The greatest source of exposure of the general population is through food, which is contaminated in minute quantities, usually measured in picograms (trillionths of a gram). Higher exposures have occurred through industrial accidents.

III. Clinical presentation

A. Acute symptoms after exposure include irritation of the skin, eyes, and mucous membranes and nausea, vomiting, and myalgias.

B. After a latency period which may be prolonged (up to several weeks or more), chloracne, porphyria cutanea tarda, hirsutism, or hyperpigmentation may occur. Elevated levels of hepatic transaminases and blood lipids may be found. Polyneuropathies with sensory impairment and lower-extremity motor weakness have been reported.

C. Death in laboratory animals occurs a few weeks after a lethal dose and is caused by a “wasting syndrome” characterized by reduced food intake and loss of body weight.

- IV. Diagnosis** is difficult and rests mainly on history of exposure; the presence of chloracne (which is considered pathognomonic for exposure to dioxins and related compounds) provides strong supporting evidence. Although 2,4,5-T no longer contains TCDD as a contaminant, possible exposures to PCDDs and PCDFs occur during many types of chemical fires (eg, PCBs), and the possibility of exposure can cause considerable public and individual anxiety.

A. Specific levels. It is difficult and expensive to detect dioxins in human blood or tissue, and there is no established correlation with symptoms. There are many congeners of PCDDs, PCDFs, and PCBs; the individual contribution of each to toxicity is unclear. Unexposed persons have a mean of 7 pg of 2,3,7,8-TCDD per g of serum lipid, compared with workers producing trichlorophenols, who had a mean of 220 pg/g. The highest recorded level is 144,000 pg/g blood fat in a patient with few adverse health effects other than chloracne.

B. Other useful laboratory studies include glucose, electrolytes, BUN, creatinine, liver transaminases and liver function tests, and uroporphyrins (if porphyria suspected).

V. Treatment

A. Emergency and supportive measures. Treat skin, eye, and respiratory irritation symptomatically.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. Inhalation. Remove victims from exposure and give supplemental oxygen if available.

2. Eyes and skin. Remove contaminated clothing and wash affected skin with copious soap and water; irrigate exposed eyes with copious tepid water or saline. Personnel involved in decontamination should wear protective gear appropriate to the suspected level of contamination.

3. Ingestion

a. Prehospital. Administer activated charcoal if available.

b. Hospital. Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. Elimination of dioxins may be enhanced by a factor of 4–7 through administration of **olestra**, a nonabsorbable fat substitute that increases fecal excretion. Olestra may decrease the half-life of elimination of TCDD from 7 years to 1–2 years.

Geusau A et al: Olestra increases faecal excretion of 2,3,7,8-tetrachlorodibenzo-p-dioxin. *Lancet* 1999;354(9186):1266–1267. [PMID: 10520643] (Two patients with chloracne and TCDD levels of 144,000 and 26,000 pg/g, treated with olestra.)

U.S. Environmental Protection Agency: Exposure and health assessment for 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and related compounds. Internet: <http://www.epa.gov/ncea/pdfs/dioxin/dioxreass.htm>

► DISULFIRAM

Richard J. Geller, MD, MPH

Disulfiram (tetraethylthiuram disulfide [CASRN 97-77-8] or Antabuse) is an antioxi-dant industrial chemical also used as a drug in the treatment of alcoholism. Ingestion of ethanol while taking disulfiram causes a well-defined unpleasant reaction, the fear of which provides a negative incentive to drink.

I. Mechanism of toxicity

- A. Disulfiram inhibits aldehyde dehydrogenase, leading to accumulation of acetaldehyde after ethanol ingestion. In addition, it inhibits dopamine betahydroxylase (necessary for norepinephrine synthesis), resulting in norepinephrine depletion at presynaptic sympathetic nerve endings and leading to vasodilation and orthostatic hypotension.
- B. Disulfiram is metabolized to small amounts of **carbon disulfide** (see also p 150), which may play a role in central and peripheral nervous system toxicity.
- C. Chronic use may increase the elimination of certain essential metals (copper, zinc) by chelation. This may, in part, be the cause of disulfiram's enzyme-inhibiting effects, as both of these enzymes require copper as a cofactor.
- D. **Pharmacokinetics.** Disulfiram is rapidly and completely absorbed, but peak effects require 8–12 hours. Although the elimination half-life is 7–8 hours, clinical actions may persist for several days. Disulfiram is metabolized in the liver; it inhibits the metabolism of many other drugs, including isoniazid, phenytoin, theophylline, warfarin, and many benzodiazepines. (See also Table II–59.)

II. Toxic dose

- A. **Disulfiram overdose.** Ingestion of 2.5 g or more has caused toxicity in children after a delay of 3–12 hours.
- B. **Disulfiram-ethanol interaction.** Ingestion of as little as 7 mL of ethanol can cause a severe reaction in patients taking as little as 200 mg/day of disulfiram. Mild reactions have been reported after use of cough syrup, after-shave lotions, and other alcohol-containing products.

III. Clinical presentation

- A. **Acute disulfiram overdose (without ethanol)** may cause vomiting, ataxia, confusion, lethargy, seizures, and coma. Hypersensitivity hepatitis has occurred, including several deaths resulting from hepatic failure.
- B. **Disulfiram-ethanol interaction.** Shortly after ingestion of ethanol, the patient receiving chronic disulfiram therapy develops flushing, throbbing headache, dyspnea, anxiety, vertigo, vomiting, and confusion. Orthostatic hypotension with warm extremities is very common. The severity of the reaction usually depends on the dose of disulfiram and ethanol. Reactions do not usually occur unless the patient has been on oral disulfiram therapy for at least 1 day; the reaction may occur up to several days after the last dose of disulfiram. Disulfiram has been implanted subcutaneously in Europe, leading to reactions after alcohol consumption that are milder but of longer duration.

IV. Diagnosis of disulfiram overdose is based on a history of acute ingestion and the presence of CNS symptoms. The disulfiram-ethanol interaction is diagnosed in a patient with a history of chronic disulfiram use and possible exposure to ethanol who exhibits a characteristic hypotensive flushing reaction.

- A. Specific levels.** Blood disulfiram levels are not of value in diagnosis or treatment. Blood acetaldehyde levels may be elevated during the disulfiram-ethanol reaction, but this information is of little value in acute management.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, and ethanol level.

V. Treatment

A. Emergency and supportive measures

1. Acute disulfiram overdose

- a. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
- b. Treat coma (see p 19) and seizures (p 22) if they occur.

2. Disulfiram-ethanol interaction

- a. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
- b. Treat hypotension with supine position and intravenous fluids (eg, saline), and treat vomiting with metoclopramide (see p 467). If a pressor agent is needed, a direct-acting agent such as norepinephrine (see p 479) is preferred over indirect-acting drugs such as dopamine.
- c. Administer benzodiazepine anxiolytics (eg, diazepam or lorazepam, p 415) and reassurance as needed.

B. Specific drugs and antidotes.

 There is no specific antidote.

C. Decontamination (see p 46)

1. Acute disulfiram overdose

- a. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting.
- b. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

2. Disulfiram-ethanol interaction.

 Decontamination procedures are not likely to be of benefit once the reaction begins.

D. Enhanced elimination.

 Hemodialysis is not indicated for disulfiram overdose, but it may remove ethanol and acetaldehyde and has been reported to be effective in treating the acute disulfiram-ethanol interaction. This is not likely to be necessary in patients receiving adequate fluid and pressor support. There are no data to support the use of repeat-dose activated charcoal for any of the disulfiram syndromes.

Anton RF: Pharmacologic approaches to the management of alcoholism. *J Clin Psychiatry* 2001;2 Suppl 20:11–17. [PMID: 11584870] (Review of animal and clinical studies of disulfiram, acamprosate, and naltrexone.)

► DIURETICS

Rita Lam, PharmD

Diuretics are commonly prescribed for the management of essential hypertension, congestive heart failure, ascites, and chronic renal insufficiency. Adverse effects from chronic use or misuse (in sports, dieting, anorexia) are more frequently encountered than those from acute overdose. Overdoses are generally benign, and no serious outcomes have resulted from acute ingestion. Common currently available diuretics are listed in Table II–23.

I. Mechanism of toxicity

- A.** The toxicity of these drugs is associated with their pharmacologic effects, which decrease fluid volume and promote electrolyte loss, including dehydration, hypokalemia (or hyperkalemia, with spironolactone), hypomagnesemia, hyponatremia, and hypochloremic alkalosis. Electrolyte imbalance may lead to cardiac arrhythmias and may enhance digitalis toxicity (see p 155). Diuret-

TABLE II-23. COMMON DIURETICS

Drug	Maximum Adult Daily Dose (mg)	Drug	Maximum Adult Daily Dose (mg)
Carbonic anhydrase inhibitors		Thiazides	
Acetazolamide	1000	Bendroflumethiazide	20
Dichlorphenamide	200	Chlorothiazide	2000
Methazolamide	300	Chlorthalidone	200
Loop diuretics		Cyclothiazide	6
Bumetanide	2	Flumethiazide	2000
Ethacrynic acid	200	Hydrochlorothiazide	200
Furosemide	600	Hydroflumethiazide	200
Torsemide	200	Indapamide	5
Potassium-sparing diuretics		Methyclothiazide	10
Amiloride	20	Metolazone	20
Spironolactone	200	Polythiazide	4
Triamterene	300	Quinethazone	200
		Trichlormethiazide	4

ics are classified based on the pharmacologic mechanisms by which they affect solute and water loss (see Table II-23).

B. Pharmacokinetics. See Table II-59, p 381.

II. Toxic dose. Minimum toxic doses have not been established. Significant dehydration or electrolyte imbalance is unlikely if the amount ingested is less than the usual recommended daily dose (see Table II-23). High doses of intravenous ethacrynic acid and furosemide can cause ototoxicity, especially when administered rapidly and in patients with renal failure.

III. Clinical presentation. Gastrointestinal symptoms including nausea, vomiting, and diarrhea are common after acute oral overdose. Lethargy, weakness, hyporeflexia, and dehydration (and occasionally hypotension) may be present if volume loss and electrolyte disturbances are present, although the onset of symptoms may be delayed for 2–4 hours or more until diuretic action is obtained. Spironolactone is very slow, with maximal effects after the third day.

A. Hypokalemia may cause muscle weakness, cramps, and tetany. Severe hypokalemia may result in flaccid paralysis and rhabdomyolysis. Cardiac rhythm disturbances may also occur.

B. Spironolactone and other potassium-sparing agents may cause hyperkalemia.

C. Hypocalcemia and hypomagnesemia may also cause tetany.

D. Hyperglycemia, hypercalcemia, and hyperuricemia may occur, especially with thiazide diuretics.

E. Carbonic anhydrase inhibitors may induce metabolic acidosis.

IV. Diagnosis is based on a history of exposure and evidence of dehydration and acid-base or electrolyte imbalance. Note that patients on diuretics may also be taking other cardiac and antihypertensive medications.

A. Specific levels are not routinely available or clinically useful.

B. Other useful laboratory studies include electrolytes (including calcium and magnesium), glucose, BUN, creatinine, and ECG.

V. Treatment

A. Emergency and supportive measures

1. Replace fluid loss with intravenous crystalloid solutions, and correct electrolyte abnormalities (see Potassium, p 37).

2. Monitor the ECG until the potassium level is normalized.

B. Specific drugs and antidotes. There are no specific antidotes.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.

2. Hospital. Administer activated charcoal. Do not use a cathartic if the patient appears dehydrated. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. No experience with extracorporeal removal of diuretics has been reported.

Lip GY, Ferner RE: Poisoning with antihypertensive drugs: diuretics and potassium supplements. *J Hum Hypertens* 1995;9(5):295–301. [PMID: 7623367] (Review.)

► ERGOT DERIVATIVES

Neal L. Benowitz, MD

Ergot derivatives are used to treat migraine headache and to enhance uterine contraction postpartum. Ergots are produced by the fungus *Claviceps purpurea*, which may grow on rye and other grains. Natural or synthetic ergot drugs include ergotamine (CafergotTM, ErgomarTM, GynergenTM, and ErgostatTM), methysergide (SansertTM), dihydroergotamine (DHE-45TM), and ergonovine (ErgotrateTM). Some ergoloid derivatives (dihydroergocornine, dihydroergocristine, and dihydroergocryptine) have been used in combination (HydergineTM and Deapril-STTM) for the treatment of dementia. Bromocriptine (ParlodelTM, see p 422) and pergolide (PermaxTM) are ergot derivatives with dopamine agonist activity used to treat Parkinson's disease. Bromocriptine is also used to treat hyperprolactinemic states.

I. Mechanism of toxicity

A. Ergot derivatives directly stimulate vasoconstriction and uterine contraction, antagonize alpha-adrenergic and serotonin receptors, and may also dilate some blood vessels via a CNS sympatholytic action. The relative contribution of each of these mechanisms to toxicity depends on the particular ergot alkaloid and its dose. **Sustained vasoconstriction** causes most of the serious toxicity; reduced blood flow causes local tissue hypoxia and ischemic injury, resulting in tissue edema and local thrombosis, worsening ischemia and causing further injury. At a certain point, reversible vasospasm progresses to irreversible vascular insufficiency and limb gangrene.

B. Pharmacokinetics. See Table II–59, p 381.

II. Toxic dose. Death has been reported in a 14-month-old child after acute ingestion of 12 mg of ergotamine. However, most cases of severe poisoning occur with chronic overmedication for migraine headaches rather than acute single overdoses. Daily doses of 10 mg or more of ergotamine are usually associated with toxicity. There are many case reports of vasospastic complications with normal therapeutic dosing.

III. Clinical presentation

A. Ergotamine and related agents. Mild intoxication causes nausea and vomiting. Serious poisoning results in vasoconstriction that may involve many parts of the body. Owing to persistence of ergots in tissues, vasospasm may continue for up to 10–14 days.

1. Involvement of the extremities causes paresthesias, pain, pallor, coolness, and loss of peripheral pulses in the hands and feet; gangrene may ensue.

2. Other complications of vasospasm include coronary ischemia and myocardial infarction, abdominal angina and bowel infarction, renal infarction and failure, visual disturbances and blindness, and stroke. Psychosis, seizures, and coma occur rarely.

B. Bromocriptine intoxication may present with hallucinations, paranoid behavior, hypertension, and tachycardia. Involuntary movements, hallucinations, and hypotension are reported with **pergolide**.

C. Chronic use of methysergide occasionally causes retroperitoneal fibrosis.

IV. Diagnosis is based on a history of ergot use and clinical findings of vasospasm.

- A. Specific levels.** Ergotamine levels are not widely available, and blood concentrations do not correlate well with toxicity.
- B. Other useful laboratory studies** include CBC, electrolytes, BUN, creatinine, and ECG. Arteriography of the affected vascular bed is occasionally indicated.

V. Treatment

A. Emergency and supportive measures

- 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
- 2. Treat coma (see p 19) and convulsions (p 22) if they occur.
- 3. Immediately discontinue ergot treatment. Hospitalize patients with vasospastic symptoms and treat promptly to prevent complications.

B. Specific drugs and antidotes

- 1. **Peripheral ischemia** requires prompt vasodilator therapy and anticoagulation to prevent local thrombosis.
 - a. Administer intravenous **nitroprusside** (see p 477), starting with 1–2 mcg/kg/min, or intravenous **phentolamine** (p 487), starting with 0.5 mg/min, increasing the infusion rate until ischemia is improved or systemic hypotension occurs. Intra-arterial infusion is occasionally required. Nifedipine or other vasodilating calcium antagonists may also enhance peripheral blood flow.
 - b. Administer **heparin**, 5000 units IV followed by 1000 units/h (in adults), with adjustments in the infusion rate to maintain the activated coagulation time (ACT) or the activated partial thromboplastin time (APTT) at approximately 2 times the baseline.
- 2. **Coronary spasm.** Administer **nitroglycerin**, 0.15–0.6 mg sublingually or 5–20 mcg/min IV. Intracoronary artery nitroglycerin may be required if there is no response to intravenous infusion. Also consider using a calcium antagonist.

C. Decontamination after acute ingestion (see p 47).

- 1. **Prehospital.** Administer activated charcoal if available. Ipecac-induced vomiting may be useful for initial treatment at the scene (eg, children at home) if it can be given within a few minutes of exposure.
- 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. Dialysis and hemoperfusion are not effective. Repeat-dose charcoal has not been studied, but because of extensive tissue distribution of ergots it is not likely to be useful.

Ausbund SC, Goodman PE: An unusual case of clarithromycin associated ergotism. *J Emerg Med* 2001;21(4):411–413. [PMID: 11728770] (Lower-extremity vasospasm due to addition of clarithromycin in a patient with longstanding use of a caffeine-ergotamine preparation for migraine.)

Vila A et al: Clinical ergotism induced by ritonavir. *Scand J Infect Dis* 2001;33(10):788–789. [PMID: 11728055] (Case report of ergotism due to concomitant use of ergotamine with ritonavir, a cytochrome P-450 inhibitor.)

► ETHANOL

Saralyn R. Williams, MD

Commercial beer, wine, and liquors contain various amounts of ethanol. Ethanol is also found in a variety of colognes, perfumes, after-shaves, mouthwashes, some rubbing alcohols, many food flavorings (eg, vanilla, almond, and lemon extracts), pharmaceutical preparations (eg, elixirs), and many other products. Ethanol is frequently ingested recreationally and is the most common co-ingestant with other

drugs in suicide attempts. Ethanol may also serve as an antidote in the emergency treatment of methanol and ethylene glycol poisonings (see p 194).

I. Mechanism of toxicity

- A. CNS depression** is the principal effect of acute ethanol intoxication. Ethanol has additive effects with other CNS depressants such as barbiturates, benzodiazepines, opioids, antidepressants, and antipsychotics.
- B. Hypoglycemia** may be caused by impaired gluconeogenesis in patients with depleted glycogen stores (particularly small children and poorly nourished persons).
- C.** Ethanol intoxication and chronic alcoholism also predispose patients to trauma, exposure-induced hypothermia, injurious effects of alcohol on the gastrointestinal tract and nervous system, and a number of nutritional disorders and metabolic derangements.
- D. Pharmacokinetics.** Ethanol is readily absorbed (peak 30–120 min) and distributed into the body water (volume of distribution 0.5–0.7 L/kg or about 50 liters in the average adult). Elimination is mainly by oxidation in the liver and follows zero-order kinetics. The average adult can metabolize about 7–10 g of alcohol per hour, or about 12–25 mg/dL/h (this rate is highly variable depending on the individual).

II. Toxic dose. Generally, 0.7 g/kg pure ethanol (approximately 3–4 drinks) will produce a blood ethanol concentration of 100 mg/dL (0.1 g/dL), legally considered intoxicated in many states.

- A.** A level of 100 mg/dL decreases reaction time and judgment and may be enough to inhibit gluconeogenesis and cause hypoglycemia in children and patients with liver disease, but by itself is not enough to cause coma.
- B.** The level sufficient to cause deep coma or respiratory depression is highly variable, depending on the individual's degree of tolerance to ethanol. Although levels above 300 mg/dL usually cause coma in novice drinkers, chronic alcoholics may be awake with levels of 500–600 mg/dL or higher.

III. Clinical presentation

A. Acute intoxication

1. With **mild** to moderate intoxication, patients exhibit euphoria, mild incoordination, ataxia, nystagmus, and impaired judgment and reflexes. Social inhibitions are loosened, and boisterous or aggressive behavior is common. Hypoglycemia may occur, especially in children and in persons with reduced hepatic glycogen stores.
2. With **deep intoxication**, coma, respiratory depression, and pulmonary aspiration may occur. In these patients, the pupils are usually small and the temperature, blood pressure, and pulse rate are often decreased. Rhabdomyolysis may result from prolonged immobility.

B. Chronic ethanol abuse is associated with numerous complications:

1. **Hepatic toxicity** includes fatty infiltration of the liver, alcoholic hepatitis, and cirrhosis. Liver scarring leads to portal hypertension, ascites, and bleeding from esophageal varices and hemorrhoids; hyponatremia from fluid retention; and bacterial peritonitis. Production of clotting factors is impaired, leading to prolonged prothrombin time (PT). Hepatic metabolism of drugs and endogenous toxins is impaired and may contribute to hepatic encephalopathy.
2. **Gastrointestinal** bleeding may result from alcohol-induced gastritis, esophagitis, and duodenitis. Other causes of massive bleeding include Mallory-Weiss tears of the esophagus and esophageal varices. Acute pancreatitis is a common cause of abdominal pain and vomiting.
3. **Cardiac** disorders include various dysrhythmias associated with potassium and magnesium depletion and poor caloric intake ("Holiday heart") and cardiomyopathy, which has been associated with long-term alcohol use as well as with ingestion of cobalt (which was once used to stabilize beer).
4. **Neurologic** toxicity includes cerebral atrophy, cerebellar degeneration, and peripheral stocking-glove sensory neuropathy. Nutritional disorders

such as thiamine (vitamin B₁) deficiency can cause Wernicke's encephalopathy or Korsakoff's psychosis.

5. **Alcoholic ketoacidosis** is characterized by anion gap metabolic acidosis and elevated levels of beta-hydroxybutyrate and, to a lesser extent, acetoacetate. The osmolar gap may also be elevated, causing this condition to be mistaken for methanol or ethylene glycol poisoning.

C. **Alcohol withdrawal.** Sudden discontinuation after chronic high-level alcohol use often causes headache, tremulousness, anxiety, palpitations, and insomnia. Brief, generalized seizures may occur, usually within 6–12 hours. Sympathetic nervous system overactivity may progress to **delirium tremens**, a life-threatening syndrome characterized by tachycardia, diaphoresis, hyperthermia, and delirium, which usually manifests 48–72 hours after cessation of heavy alcohol use. The "DTs" may cause significant morbidity and mortality if untreated.

D. **Other problems.** Ethanol abusers sometimes intentionally or accidentally ingest ethanol substitutes such as isopropyl alcohol (see p 234), methanol (p 260), or ethylene glycol (p 194). In addition, ethanol may serve as the vehicle for swallowing large numbers of pills in a suicide attempt. Disulfiram (p 186) use can cause a serious acute reaction with ethanol.

IV. **Diagnosis** of ethanol intoxication is usually simple, based on the history of ingestion, the characteristic smell of fresh alcohol or the fetid odor of acetaldehyde and other metabolic products, and the presence of nystagmus, ataxia, and altered mental status. However, other disorders may accompany or mimic intoxication, such as hypoglycemia, head trauma, hypothermia, meningitis, or intoxication with other drugs or poisons.

A. **Specific levels.** Serum ethanol levels are easily and rapidly determined by most hospital laboratories and, depending on the method used, are accurate and specific.

1. In general, there is only rough correlation between blood levels and clinical presentation; however, an ethanol level below 300 mg/dL in a comatose patient should initiate a search for alternative causes.
2. If ethanol levels are not readily available, the ethanol concentration may be estimated by calculating the osmolar gap (see p 32).

B. **Suggested laboratory studies** may include glucose, electrolytes, BUN, creatinine, liver transaminases, prothrombin time (PT/INR), magnesium, arterial blood gases or oximetry, and chest x-ray (if pulmonary aspiration is suspected). Consider CT scan of the head if the patient has focal neurological deficits or altered mental status inconsistent with the degree of blood alcohol elevation.

V. Treatment

A. Emergency and supportive measures

1. **Acute intoxication.** Treatment is mainly supportive.

- a. Protect the airway to prevent aspiration and intubate and assist ventilation if needed (pp 1–7).
- b. Give glucose and thiamine (see pp 450 and 505), and treat coma (p 19) and seizures (p 22) if they occur. Glucagon is not effective for alcohol-induced hypoglycemia.
- c. Correct hypothermia with gradual rewarming (see p 20).
- d. Most patients will recover within 4–6 hours. Observe children until their blood alcohol level is below 50 mg/dL and there is no evidence of hypoglycemia.

2. **Alcoholic ketoacidosis.** Treat with volume replacement, thiamine (see p 505), and supplemental glucose. Most patients recover rapidly.

3. **Alcohol withdrawal.** Treat with benzodiazepines (eg, diazepam, 2–10 mg IV initially, repeated as needed; see p 415).

B. **Specific drugs and antidotes.** There is no available specific ethanol receptor antagonist, despite anecdotal reports of arousal after administration of naloxone.

C. Decontamination (see p 46)

1. **Prehospital.** Do not induce vomiting or administer activated charcoal.
2. **Hospital.** Because ethanol is rapidly absorbed, gastric lavage is usually not indicated unless other drug ingestion is suspected. Consider lavage only if the alcohol ingestion was massive and recent (within 30–45 minutes). Activated charcoal does not effectively adsorb ethanol but may be given if other toxins were ingested.

D. Enhanced elimination. Metabolism of ethanol normally occurs at a fixed rate of approximately 20–30 mg/dL/h. Elimination rates are faster in chronic alcoholics and at serum levels above 300 mg/dL. Hemodialysis efficiently removes ethanol, but enhanced removal is rarely needed because supportive care is usually sufficient. Hemoperfusion and forced diuresis are not effective.

Feeney C et al: Reversible blindness associated with alcoholic ketoacidosis: pseudomethanol intoxication. *J Emerg Med* 1998;16(4):597–599. [PMID: 9696177] (A 49-year-old woman with severe metabolic acidosis and acute blindness which resolved with symptomatic treatment. Ethanol was 14.76 mmol/L, and there was no detectable methanol.)

Olmedo R, Hoffman RS: Withdrawal syndromes. *Emerg Med Clin North Am* 2000;18(2):273–288. [PMID: 10767884] (Overview of different withdrawal syndromes with emphasis on ethanol.)

► ETHYLENE DIBROMIDE

Janet Weiss, MD

Ethylene dibromide (EDB or dibromoethane) is a volatile liquid produced by the bromination of ethylene. EDB is used as a lead scavenger in leaded gasoline and as a pesticide and fumigant in soil and on grain, fruits, and vegetables. Because EDB has been classified as a suspected human carcinogen and is a male reproductive toxin, its use as a pesticide has been restricted since 1984.

I. Mechanism of toxicity

- A. **Liquid EDB is an irritant** capable of causing chemical burns. Inhalation of EDB vapor produces respiratory tract irritation and delayed-onset pulmonary edema.
- B. **Once absorbed systemically**, EDB is converted to active metabolites that become irreversibly bound to macromolecules, including DNA, and inhibit enzymes. Metabolism of EDB involves an oxidative pathway (cytochrome P-450) and a conjugation pathway (glutathione). The liver is a principal target organ for toxicity.

II. Toxic dose

- A. **Inhalation.** Because EDB is a suspected carcinogen (ACGIH category A2), no “safe” workplace exposure limit has been determined. Although the current OSHA legal permissible exposure limit (PEL) is 20 ppm as an 8-hour time-weighted average with a ceiling of 30 ppm, the National Institute for Occupational Safety and Health (NIOSH) recommends a ceiling exposure of no more than 0.13 ppm. Exposure to vapor concentrations greater than 200 ppm can produce lung irritation, and 400 ppm is the air level considered immediately dangerous to life or health (IDLH).
- B. **Ingestion** of 4.5 mL of liquid EDB (160 mg/kg) resulted in death.
- C. Dermal application of as little as 16 mg/kg caused systemic intoxication.
- D. The US Environmental Protection Agency (EPA) drinking-water Maximum Contaminant Limit (MCL) for EDB is 0.00005 mg/L.

III. Clinical presentation

- A. **Inhalation** of EDB vapor causes irritation of the eyes and upper respiratory tract. Pulmonary edema usually occurs within 1–6 hours but may be delayed as long as 48 hours after exposure.
- B. **Skin exposure** produces painful local inflammation, swelling, and blistering.

- C. **Oral ingestion** causes prompt vomiting and diarrhea.
 - D. **Systemic** manifestations of intoxication include CNS depression, delirium, seizures, and metabolic acidosis. Skeletal muscle necrosis, acute renal failure, and hepatic necrosis have also been reported in fatal cases.
- IV. **Diagnosis** of EDB poisoning is based on a history of exposure and evidence of upper-airway and eye irritation (in cases of inhalation) or gastroenteritis (after ingestion). EDB vapor has a strong chemical odor.
- A. **Specific levels.** EDB is detectable in expired air, blood, and tissues, although levels are not useful in emergency management. Serum bromide levels may be elevated (> 0.1 mEq/L) in severe cases, because bromide is released from EDB in the body.
 - B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, CPK, arterial blood gases, and chest x-ray.
- V. **Treatment**
- A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. After inhalation exposure, anticipate and treat wheezing, airway obstruction, and pulmonary edema (pp 7–8). Monitor blood gases, provide supplemental oxygen if needed, and avoid fluid overload.
 3. Treat coma (see p 19), seizures (p 22), rhabdomyolysis (p 27), and metabolic acidosis (p 33) if they occur.
 - B. **Specific drugs and antidotes.** There is no specific antidote.
 - C. **Decontamination** (see p 46). **Caution:** Rescuers should use self-contained breathing apparatus and wear protective clothing to avoid personal exposure.
 1. **Inhalation.** Remove the victim from exposure and provide supplemental oxygen if available.
 2. **Skin and eyes.** Remove and safely discard all contaminated clothing, and wash exposed skin with copious soap and water. Irrigate exposed eyes with tepid saline or water.
 3. **Ingestion**
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of corrosive effects and the risk of rapid onset of coma or seizures.
 - b. **Hospital.** Perform gastric lavage if the patient presents within 30 minutes of ingestion or has ingested a large quantity (more than 1–2 oz). Administer activated charcoal.
 - D. **Enhanced elimination.** There is no role for dialysis or hemoperfusion, diuresis, or repeat-dose charcoal.

► ETHYLENE GLYCOL AND OTHER GLYCOLS

Ilene B. Anderson, PharmD

Ethylene glycol is the primary ingredient (up to 95%) in antifreeze. It is sometimes intentionally consumed as an alcohol substitute by alcoholics and is tempting to children because of its sweet taste. Intoxication by ethylene glycol itself causes inebriation and mild gastritis; in addition, its metabolic products cause metabolic acidosis, renal failure, and death. Other glycols may also produce toxicity (Table II–24).

I. Mechanism of toxicity

- A. **Ethylene glycol** is metabolized by alcohol dehydrogenase to glycoaldehyde, which is then metabolized to glycolic, glyoxylic, and oxalic acids. These acids,

TABLE II-24. TOXICITY OF OTHER GLYCOLS

Compounds	Toxicity and Comments	Treatment
Propylene glycol	Relatively low toxicity. Lactic acidosis, central nervous system depression, coma, hypoglycemia, seizures, and hemolysis have been reported rarely after massive exposures or chronic exposures in high-risk patients. Risk factors include: renal insufficiency, small infants, epilepsy, or burn patients with extensive dermal application of propylene glycol. Osmolar gap, anion gap, and lactate are commonly elevated. Levels: 70 mg/dL was associated with lactic acidosis and central nervous system depression in a patient with azotemia; 78 mg/dL was associated with lactic acidosis, elevated osmolar gap following prolonged infusion in a patient with normal renal function; 6–42 mg/dL did not result in toxicity after acute infusion; 70 mg/dL resulted in lactic acidosis with a lactate level equal to 24 meq/L without an osmolar gap following chronic infusion; 1059 mg/dL was reported in an 8-month-old with extensive burn injuries after repeated dermal application (the child experienced cardiopulmonary arrest); 400 mg/dL was measured in an epileptic patient who experienced status epilepticus, respiratory depression, elevated osmolar gap, and metabolic acidosis. Metabolites are lactate and pyruvate. Molecular weight is 76.	Supportive care, sodium bicarbonate. There is no role for ethanol therapy. Hemodialysis is effective but rarely indicated.
Dipropylene glycol	Relatively low toxicity. Central nervous system depression, hepatic injury, and renal damage have occurred in animal studies after massive exposures. There are no reports of acidosis or lactate elevation. Molecular weight is 134.	Supportive care. There is no role for ethanol therapy.
Polyethylene glycols	Very low toxicity. A group of compounds with molecular weights ranging from 200 to more than 4000. High-molecular-weight compounds (>500) are poorly absorbed and are rapidly excreted by the kidneys. Low-molecular-weight compounds (200–400) may result in metabolic acidosis, renal failure, hypercalcemia after massive oral ingestions or repeated dermal applications in patients with extensive burn injuries. Alcohol dehydrogenase metabolizes polyethylene glycols.	Supportive care.
Diethylene glycol	Highly nephrotoxic; similar to ethylene glycol. Renal failure, coma, acidosis, and death have been reported in 5 patients with extensive burn injuries after repeated dermal application. Vomiting, diarrhea, renal failure, metabolic acidosis, hepatitis, pancreatitis, coma, and death reported after ingestion. Calcium oxalate crystals have been seen in animal studies. Molecular weight is 106.	Ethanol and fomepizole may be effective.

(continued)

TABLE II-24. TOXICITY OF OTHER GLYCOLS (CONTINUED)

Compounds	Toxicity and Comments	Treatment
Ethylene glycol mono butyl ether (EGBE, 2-butoxy-ethanol, butyl cellosolve).	Oxalate crystals, renal dysfunction, and increased osmolar gap may or may not occur. Levels of 432 mcg/mL have been associated with coma, hypotension, and acidosis without an osmolar gap, oxalate crystals, or renal dysfunction. ARDS has been reported in one patient. Animal studies indicate that EGBE is metabolized in part to ethylene glycol and that pyrazole (an alcohol dehydrogenase blocker) prevents toxicity, but the affinity of alcohol dehydrogenase for EGBE is unknown. Molecular weight is 118.	Ethanol and fomepizole may be effective.
Ethylene glycol mono ethyl ether (EGEE, ethyl cellosolve)	Calcium oxalate crystals have been reported in animals. Animal studies indicate that EGEE is metabolized in part to ethylene glycol; however, the affinity of alcohol dehydrogenase is higher for EGEE than for ethanol. Teratogenic effect has been reported in humans and animals. Molecular weight is 90.	Ethanol and fomepizole may be effective.
Ethylene glycol mono methyl ether (EGME, methyl cellosolve)	Delayed toxic effects (8 and 18 hours postingestion) similar to ethylene glycol have been reported. Calcium oxalate crystals may or may not occur. Cerebral edema, hemorrhagic gastritis, and degeneration of the liver and kidneys were reported in one autopsy. Animal studies indicate that EGME is metabolized in part to ethylene glycol; however, the affinity of alcohol dehydrogenase is about the same for EGME as for ethanol. Oligospermia has been reported with chronic exposure in humans. Teratogenic effects have been reported in animals. Molecular weight is 76.	Ethanol and fomepizole may be effective.
Dioxane (dimer of ethylene glycol)	May cause coma, liver and kidney damage. The vapor (> 300 ppm) may cause mucous membrane irritation. Dermal exposure to the liquid may have a defatting action. Metabolites unknown. Molecular weight is 88.	Role of ethanol and fomepizole is unknown, but they may be effective.
Triethylene glycol	Coma, metabolic acidosis with elevated anion gap, osmolar gap of 7 mOsm/L reported 1–1.5 hours after an ingestion. Treated with ethanol and recovered by 36 hours.	Ethanol and fomepizole may be effective.

along with excess lactic acid, are responsible for the anion gap metabolic acidosis. Oxalate readily precipitates with calcium to form insoluble calcium oxalate crystals. Tissue injury is caused by widespread deposition of oxalate crystals and the toxic effects of glycolic and glyoxylic acids.

B. Pharmacokinetics. Ethylene glycol is well absorbed. The volume of distribution (Vd) is about 0.8 L/kg. It is not protein bound. Metabolism is by alcohol dehydrogenase with a half-life of about 3–5 hours. In the presence of ethanol or fomepizole (see below), which block ethylene glycol metabolism, elimination is entirely renal with a half-life of about 17 hours.

C. Other glycols (see Table II–24). Propylene and dipropylene glycols are of relatively low toxicity. Polypropylene glycol and other high-molecular-weight polyethylene glycols are poorly absorbed and virtually nontoxic. However, diethylene glycol and glycol ethers produce toxic metabolites with toxicity similar to that of ethylene glycol.

II. Toxic dose. The approximate lethal oral dose of 95% ethylene glycol (eg, antifreeze) is 1.5 mL/kg; however, survival has been reported after an ingestion of 2 L in a patient who received treatment within 1 hour of ingestion.

III. Clinical presentation

A. Ethylene glycol

1. **During the first few hours** after acute ingestion, the victim may appear intoxicated as if by ethanol. The osmolar gap (see p 32) is increased, but there is no initial acidosis. Gastritis with vomiting may also occur.

2. **After a delay of 4–12 hours**, evidence of intoxication by metabolic products occurs, with anion gap acidosis, hyperventilation, convulsions, coma, cardiac conduction disturbances, and arrhythmias. Renal failure is common but usually reversible. Pulmonary edema and cerebral edema may also occur. Hypocalcemia with tetany has been reported.

B. Other glycols (see Table II–24). Diethylene glycol and glycol ethers are extremely toxic and may produce acute renal failure and metabolic acidosis. Calcium oxalate crystals may or may not be present.

IV. Diagnosis of ethylene glycol poisoning is usually based on the history of antifreeze ingestion, typical symptoms, and elevation of the osmolar and anion gaps. Oxalate or hippurate crystals may be present in the urine (crystals may be cuboidal or elongate in form). Because many antifreeze products contain fluorescein, the urine may fluoresce under Wood's lamp, depending on the amount ingested, the time since ingestion, and the urine concentration.

A. Specific levels. Tests for ethylene glycol levels are usually available from regional commercial toxicology laboratories but are difficult to obtain quickly.

1. Serum levels higher than 50 mg/dL are usually associated with serious intoxication, although lower levels do not rule out poisoning if the parent compound has already been metabolized (in such a case, the anion gap should be markedly elevated). Calculation of the osmolar gap (see p 32) may be used to estimate the ethylene glycol level.

2. False-positive ethylene glycol levels can be caused by elevated triglycerides (see Table I–33, p 43) or 2,3-butanediol in some assays.

3. Elevated concentrations of the toxic metabolite **glycolic acid** are a better measure of toxicity but are not yet widely available. Levels less than 10 mmol/L are not toxic.

4. In the absence of a serum ethylene glycol level, if the osmolar and anion gaps are both normal and the patient is asymptomatic, then serious ingestion is not likely to have occurred.

B. Other useful laboratory studies include electrolytes, lactate, ethanol, glucose, BUN, creatinine, calcium, hepatic transaminases, urinalysis (for crystals and Wood's lamp examination), measured osmolality, arterial blood gases, and ECG monitoring. Serum **beta-hydroxybutyrate** levels may help distinguish ethylene glycol poisoning from **alcoholic ketoacidosis**, which may also cause increased anion and osmolar gaps. (Patients with alcoholic ke-

toacidosis may not have markedly positive tests for ketones, but the beta-hydroxybutyrate level will usually be elevated.)

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat coma (see p 19), convulsions (p 22), cardiac arrhythmias (pp 10–15), and metabolic acidosis (p 33) if they occur. Observe the patient for several hours to monitor for development of metabolic acidosis, especially if the patient is symptomatic or there is known co-ingestion of ethanol.
3. Treat hypocalcemia with intravenous calcium gluconate or calcium chloride (see p 424).

B. Specific drugs and antidotes

1. Administer **fomepizole** (see p 448) or **ethanol** (p 444) to saturate the enzyme alcohol dehydrogenase and prevent metabolism of ethylene glycol to its toxic metabolites. Indications for therapy include the following:
 - a. Ethylene glycol level higher than 20 mg/dL.
 - b. History of ethylene glycol ingestion accompanied by two or more of the following:
 - (1) Osmolar gap greater than 10 mOsm/L not accounted for by ethanol or other alcohols.
 - (2) Serum bicarbonate less than 20 mEq/L.
 - (3) Arterial pH less than 7.3.
 - (4) Presence of oxalate crystals in the urine.
2. Administer **pyridoxine** (see p 499), **folate** (p 447), and **thiamine** (p 505), cofactors required for the metabolism of ethylene glycol that may alleviate toxicity by enhancing metabolism of glyoxylic acid to nontoxic metabolites.

C. Decontamination (see p 46)

1. **Prehospital.** Do not induce vomiting or administer activated charcoal.
2. **Hospital.** Gastric lavage may be useful if instituted within 30–60 minutes of the ingestion. Activated charcoal is not likely to be of benefit because the required effective dose is large and ethylene glycol is rapidly absorbed.

D. Enhanced elimination. The volume of distribution of ethylene glycol is 0.7–0.8 L/kg, making it accessible to enhanced elimination procedures. **Hemodialysis** efficiently removes ethylene glycol and its toxic metabolites and rapidly corrects acidosis and electrolyte and fluid abnormalities.

1. Indications for hemodialysis include:

- a. Suspected ethylene glycol poisoning with an osmolar gap greater than 10 mOsm/L not accounted for by ethanol or other alcohols.
- b. Ethylene glycol intoxication accompanied by renal failure.
- c. Ethylene glycol serum concentration greater than 50 mg/dL, unless the patient is asymptomatic and receiving fomepizole or ethanol therapy.
- d. Severe metabolic acidosis in a patient with a history of ethylene glycol ingestion, even if the osmolar gap is not elevated (late presenter).

2. Endpoint of treatment. The minimum serum concentration of ethylene glycol associated with serious toxicity is not known. In addition, ethylene glycol levels are reported to rebound after dialysis ceases. Therefore, treatment with fomepizole or ethanol should be continued until the osmolar and anion gaps are normalized or (if available) serum ethylene glycol and glycolic acid levels are no longer detectable.

Barceloux DG et al: American Academy of Clinical Toxicology Practice Guidelines on the Treatment of Ethylene Glycol Poisoning. Ad Hoc Committee. *J Toxicol Clin Toxicol* 1999;37(5):537–560. [PMID: 10497633] (Overview of clinical presentation, diagnosis, and treatment of EG poisoning.)

O'Brien KL et al: Epidemic of pediatric deaths from acute renal failure caused by diethylene glycol poisoning. Acute Renal Failure Investigation Team. *JAMA* 1998;279(15):1175–1180. [PMID: 9555756] (Case series of 109 children with severe poisoning from improperly formulated acetaminophen syrup containing 14% diethylene glycol; 88 of the children died.)

► ETHYLENE OXIDE

Stephen C. Born, MD, MPH

Ethylene oxide is a highly penetrating flammable gas or liquid, widely used as a sterilizer of medical equipment and supplies. It is also an important industrial chemical, used as a solvent, plasticizer, and chemical intermediate. Ethylene oxide liquid has a boiling point of 10.7°C (760 mm Hg), and is readily miscible with water and organic solvents.

- I. **Mechanism of toxicity.** Ethylene oxide is an alkylating agent and reacts directly with proteins and DNA to cause cell death. Direct contact with the gas causes irritation of the eyes, mucous membranes, and lungs. Ethylene oxide is mutagenic, teratogenic, and carcinogenic (regulated as a carcinogen by OSHA; IARC group 1 [carcinogenic to humans]). Ethylene oxide may be absorbed through intact skin.
- II. **Toxic dose.** The recommended workplace limit (ACGIH TLV-TWA) in air is 1 ppm (1.8 mg/m³) as an 8-hour time-weighted average. The air level immediately dangerous to life or health (IDLH) is 800 ppm. The odor threshold is approximately 700 ppm, giving the gas poor warning properties. High levels of ethylene oxide can occur when sterilizers malfunction or with the opening or replacing of ethylene oxide tanks. Exposure may also occur when fumigated or sterilized materials are inadequately aerated. A minute amount of ethylene oxide is produced endogenously in humans from the metabolism of ethylene. Occupational exposure above OSHA-determined trigger levels requires medical surveillance (29 CFR 1910.1047).
- III. **Clinical presentation**
 - A. Ethylene oxide is a potent mucous membrane irritant and can cause eye and oropharyngeal irritation, bronchospasm, and pulmonary edema. Cataract formation has been described after significant eye exposure. Exposure to the liquid can cause vesicant injury to the skin.
 - B. Neurotoxicity, including convulsions and delayed peripheral neuropathy, may occur after exposure.
 - C. Other systemic effects include cardiac arrhythmias when ethylene oxide is used in combination with freon (see p 209) as carrier gas.
 - D. Leukemia has been described in workers chronically exposed to relatively low levels of ethylene oxide.
- IV. **Diagnosis** is based on a history of exposure and typical upper-airway irritant effects. Detection of ethylene oxide odor indicates significant exposure. Industrial hygiene sampling is necessary to document air levels of exposure.
 - A. **Specific levels.** Blood levels are not available. Ethylene oxide DNA adducts may indicate exposure but are not available for clinical use.
 - B. **Other useful laboratory studies** include arterial blood gases or pulse oximetry and chest x-ray.
- V. **Treatment**
 - A. **Emergency and supportive measures.** Monitor closely for several hours after exposure.
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Treat bronchospasm (p 8) and pulmonary edema (p 7) if they occur.
 2. Treat coma (see p 19), convulsions (p 22), and arrhythmias (pp 10–15) if they occur.
 - B. **Specific drugs and antidotes.** There is no specific antidote.
 - C. **Decontamination** (see p 46)
 1. Remove the victim from the contaminated environment immediately and administer oxygen. Rescuers should wear self-contained breathing apparatus and chemical-protective clothing.
 2. Remove all contaminated clothing and wash exposed skin. For eye exposures, irrigate copiously with tepid water or saline.
 - D. **Enhanced elimination.** There is no role for these procedures.

► **FLUORIDE**
Kathryn H. Meier, PharmD

Fluoride-liberating chemicals are used in some automobile wheel cleaners, glass etching solutions, insecticides, rodenticides, aluminum production, vitamins or dietary supplements, and products to prevent dental caries. Most toothpaste contains up to 5 mg fluoride per teaspoon. Fluoride is commonly added to community drinking water. It is also found in hydrofluoric acid (see p 221), which is used for etching glass and cleaning silicon chip products. Soluble fluoride salts are rapidly absorbed and are more acutely toxic (Table II–25).

- I. Mechanism of toxicity**
- A.** In addition to its direct cytotoxic and metabolic effects, fluoride binds avidly to calcium and magnesium causing hypocalcemia and hypomagnesemia. Fluoride disrupts many intracellular mechanisms including glycolysis, G-protein–mediated signaling, oxidative phosphorylation, ATP production, function of Na/K-ATPase, and potassium channels.
- B. Pharmacokinetics.** Fluoride is a weak acid (pKa 3.4) that is passively absorbed from the stomach and small intestine. In an acidic environment more fluoride is present as HF, which is more rapidly absorbed. Fasting peak absorption occurs in 30–60 minutes. The volume of distribution is 0.5–0.7 L/kg. Fluoride is not protein bound, but binds readily to magnesium and calcium in blood, tissues, and bone (most fluoride in the body is bound to bone). The elimination half-life is 2.4–4.3 hours and is prolonged in patients with renal failure.
- II. Toxic dose.** Vomiting and abdominal pain are common with ingestions of 3–5 mg/kg elemental fluoride (see Table II–25); hypocalcemia and muscular symptoms appear with ingestions of 5–10 mg/kg. Death has been reported in a 3-year-old child after ingestion of 16 mg/kg and in adults with doses in excess of 32 mg/kg.
- III. Clinical presentation**
- A. Acute poisoning.** Nausea and vomiting frequently occur within 30–60 minutes of ingestion. Symptoms of serious intoxication include skeletal muscle weakness, tetanic contractions, respiratory muscle weakness, and respiratory arrest. Laboratory findings include hypocalcemia, hypomagnesemia, and hyperkalemia, and increased QT interval and cardiac dysrhythmias may occur.

TABLE II–25. FLUORIDE-CONTAINING COMPOUNDS

Compound	Elemental Fluoride (%)
Soluble salts	
Ammonium bifluoride	67
Hydrogen fluoride	95
Sodium fluoride	45
Sodium fluosilicate	61
Less soluble salts	
Cryolite	54
Sodium monofluorophosphate	13
Stannous fluoride	24

- B. Chronic effects.** Minor overexposure in children under age 10 can cause tooth mottling. High chronic overexposure (more than 20 mg/day for more than 10 years) can cause skeletal fluorosis (osteosclerosis), ligament calcification, and increased bone density.
- IV. Diagnosis** is usually based on a history of ingestion. Symptoms of gastrointestinal distress, muscle weakness, hypocalcemia, and hyperkalemia suggest fluoride intoxication.
- A. Specific levels.** The normal serum fluoride concentration is less than 20 mcg/L (ng/mL) but varies considerably with diet and water source. Serum fluoride concentrations are generally difficult to obtain and thus are of limited utility for acute overdose management.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, calcium (and ionized calcium), magnesium, and ECG.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Monitor ECG and serum calcium, magnesium, and potassium for at least 4–6 hours. Admit symptomatic patients with ECG or electrolyte abnormalities to an intensive care setting.
- B. Specific drugs and antidotes.** When clinically significant hypocalcemia is present, administer **intravenous calcium gluconate** (see p 424), 10–20 mL (children: 0.2–0.3 mL/kg), and monitor ionized calcium levels and titrate further doses as needed. Treat hypomagnesemia with intravenous **magnesium sulfate**, 1–2 g given over 10–15 min (children: 25–50 mg/kg diluted to less than 10 mg/mL). Treat hyperkalemia with intravenous calcium and other usual measures (p 37).
- C. Decontamination** (see p 47)
1. **Prehospital.** Do **not** induce vomiting because of the risk of abrupt onset of seizures and arrhythmias. Administer an antacid containing **calcium** (eg, calcium carbonate [Tums, Rolaids]) orally to raise gastric pH and complex free fluoride, reducing absorption. Foods rich in calcium (eg, milk) can also bind fluoride. Magnesium-containing antacids have also been recommended but there are little data for their effectiveness.
 2. **Hospital.** Administer antacids containing **calcium** as described above. Consider gastric lavage for large recent ingestions. Activated charcoal does not adsorb fluoride and is not likely to be beneficial.
- D. Enhanced elimination.** Because fluoride rapidly binds to free calcium and bone and has a short elimination half-life, hemodialysis is not likely to be effective.

Heard K et al: Calcium neutralizes fluoride bioavailability in a lethal model of fluoride poisoning. *J Toxicol Clin Toxicol* 2001;39(4):349–353. [PMID: 11527228] (Animal model of lethal fluoride poisoning by intraperitoneal injection showed benefit with co-administered calcium but not magnesium salts.)

► FLUOROACETATE

Steve Offerman, MD

Fluoroacetate, also known as compound 1080, sodium monofluoroacetate (SMFA), and sodium fluoroacetate, is one of the most toxic substances known. In the past, it was used primarily as a rodenticide by licensed pest control companies, but it has been removed from the US market because of its hazard. (However, it is still used as packets attached to sheep to poison wolves and coyotes that kill and ingest the sheep.) It is a tasteless, odorless, water-soluble white crystalline powder. Fluoroacetamide (compound 1081) is a similar compound with similar toxicity.

I. Mechanism of toxicity

A. Fluoroacetate is metabolized to the toxic compound fluorocitrate, which blocks cellular metabolism by inhibiting the aconitase enzyme within the Krebs cycle. Clinical effects of poisoning are delayed (from 30 minutes to several hours) until fluoroacetate is metabolized to fluorocitrate.

B. Pharmacokinetics. The onset of effect is reported to be 30 minutes to several hours after ingestion. The time to peak effect, volume of distribution (Vd), duration of action, and elimination half-life in humans are unknown, but there are reports of late-onset coma (36 hours). In rats, only 1% of an oral dose is excreted in the urine and feces within 5 hours and only 12% by 48 hours.

II. Toxic dose. Inhalation or ingestion of as little as 1 mg of fluoroacetate is sufficient to cause serious toxicity. Death is likely after ingestion of more than 5 mg/kg.

III. Clinical presentation. After a delay of minutes to several hours (in one report coma was delayed 36 hours), manifestations of diffuse cellular poisoning become apparent; nausea, vomiting, diarrhea, metabolic acidosis, renal failure, agitation, confusion, seizures, coma, respiratory arrest, pulmonary edema, and ventricular arrhythmias may occur. One case series reported a high incidence of hypocalcemia and hypokalemia.

IV. Diagnosis is based on a history of ingestion and clinical findings, which may be delayed for several hours. Poisoning with fluoroacetate may mimic poisoning with other cellular toxins such as hydrogen cyanide and hydrogen sulfide, although with these poisons the onset of symptoms is usually more rapid.

A. Specific levels. There is no assay available.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, calcium, arterial blood gases, ECG, and chest x-ray. Perform continuous ECG monitoring.

V. Treatment**A. Emergency and supportive measures**

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.

2. Replace fluid losses from gastroenteritis with intravenous saline or other crystalloids.

3. Treat shock (see p 16), seizures (p 22), and coma (p 19) if they occur. Because of the reported potential delay in onset of serious symptoms, it is prudent to monitor the patient for at least 36–48 hours.

B. Specific drugs and antidotes. There is no available antidote. Monoacetin (glyceryl monoacetate), which decreases conversion of fluoroacetate to fluorocitrate, has been used experimentally in monkeys, but is not available or recommended for human use.

C. Decontamination (see p 47)

1. **Prehospital.** If it is available, immediately administer activated charcoal. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).

2. **Hospital.** Immediately administer activated charcoal. Consider gastric lavage if it can be performed within 60 minutes of ingestion.

3. **Skin exposure.** Fluoroacetate is poorly absorbed through intact skin, but a significant exposure could occur through broken skin. Remove contaminated clothing and wash exposed skin thoroughly.

D. Enhanced elimination. There is no role for any enhanced removal procedure.

Chi CH et al: Clinical presentation and prognostic factors in sodium monofluoroacetate intoxication. *J Toxicol Clin Toxicol* 1996;34(6):707–712. [PMID: 8941201] (Retrospective review of 38 cases found 18% mortality. Hypotension, metabolic acidosis, and increased creatinine were important predictors of mortality.)

Robinson RF et al: Intoxication with sodium monofluoroacetate (compound 1080). *Vet Hum Toxicol* 2002;44(2):93–95. [PMID: 11931513] (Case report included early onset seizure, late onset coma, eventual full recovery over 5 days.)

► FOOD POISONING: BACTERIAL

Susan Kim, PharmD

Food-borne bacteria and bacterial toxins are a common cause of epidemic food-borne gastroenteritis. In general, the illness is relatively mild and self-limited, with recovery within 24 hours. However, severe and even fatal poisoning may occur with listeriosis, salmonellosis, or **botulism** (see p 136), and with certain strains of *Escherichia coli*. Poisoning after the consumption of **fish and shellfish** is discussed on p 205. **Mushroom** poisoning is discussed on p 271. **Viruses** such as the Norwalk virus and Norwalk-like caliciviruses, enteroviruses, and rotaviruses can also be transmitted through food and are the causative agent in as many as 80% of food-related illness. Other microbes that can cause food-borne illness include *Cryptosporidium* and *Cyclospora*, which can cause serious illness in immunocompromised patients.

- I. **Mechanism of toxicity.** Gastroenteritis may be caused by invasive bacterial infection of the intestinal mucosa or by a toxin elaborated by bacteria. Bacterial toxins may be preformed in food that is improperly prepared and improperly stored before use, or may be produced in the gut by the bacteria after they are ingested (Table II–26).
- II. **Toxic dose.** The toxic dose depends on the type of bacteria or toxin and its concentration in the ingested food, as well as individual susceptibility or resistance. Some of the preformed toxins (eg, staphylococcal toxin) are heat resistant and once in the food are not removed by cooking or boiling.
- III. **Clinical presentation.** Commonly, a delay or “incubation period” of from 2 hours to 3 days precedes the onset of symptoms (see Table II–26).
 - A. **Gastroenteritis** is the most common finding, with nausea, vomiting, abdominal cramps, and diarrhea. Vomiting is more common with preformed toxins. Significant fluid and electrolyte abnormalities may occur, especially in young children or elderly patients.
 - B. **Fever, bloody stools, and fecal leukocytosis** are common with invasive bacterial infections. However, fecal leukocytes may be absent.
 - C. **Systemic infection** can result from *E coli*, *Salmonella*, *Shigella*, *Campylobacter*, or *Listeria*.
 1. **Listeriosis** can cause sepsis and meningitis, particularly in elderly and immunocompromised persons. Infection during pregnancy produces a mild, flu-like illness in the mother but serious intrauterine infection resulting in fetal death, neonatal sepsis, or meningitis.
 2. ***Shigella* and *E coli* 0157:H7** strain may cause acute hemorrhagic colitis complicated by hemolytic-uremic syndrome, renal failure, and death, especially in children or immunocompromised adults.
 3. ***Campylobacter*** infections can sometimes be followed by Guillain-Barré syndrome or reactive arthritis.
- IV. **Diagnosis.** Bacterial food poisoning is often difficult to distinguish from common viral gastroenteritis, unless the incubation period is short and there are multiple victims who ate similar foods at one large gathering. The presence of many white blood cells in a stool smear suggests invasive bacterial infection. With any epidemic gastroenteritis, consider other food-borne illnesses, such as those caused by viruses, illnesses associated with seafood (see p 205), botulism (p 136), and illnesses related to ingestions of certain mushrooms (p 271).
 - A. **Specific levels**
 1. **Stool culture** may differentiate *Salmonella*, *Shigella*, and *Campylobacter* infections. However, culture for *E coli* 0157:H7 must be specifically requested. An ELISA test can detect Norwalk virus in stools.
 2. **Blood and CSF** may grow invasive organisms, especially *Listeria* (and rarely, *Salmonella* or *Shigella*).
 3. **Food samples** should be saved for bacterial culture and toxin analysis, primarily for use by public health investigators.

TABLE II-26. SUMMARY OF BACTERIAL FOOD POISONING

Organism	Incubation Period	Common Symptoms ^a & Mechanism	Common Foods
<i>Bacillus cereus</i>	1–6 h (emesis) 8–16 h (diarrhea)	V > D. Toxins produced in food and gut.	Reheated fried rice.
<i>Campylobacter jejuni</i>	1–8 d	D+, F. Invasive and possibly toxin produced in gut.	Water; milk; direct contact (eg, food handlers).
<i>Clostridium perfringens</i>	6–16 h	D > V. Toxin produced in food and gut.	Meats, gravy.
<i>Escherichia coli</i> “enterotoxigenic”	12–72 h	D > V. Toxin produced in gut.	“Traveler’s diarrhea.” Water, various foods; direct contact (eg, food handlers).
<i>Escherichia coli</i> “enteroinvasive”	24–72 h	D+. Invasive infection.	Water, various foods; direct contact (eg, food handlers).
<i>Escherichia coli</i> “enterohemorrhagic” O157:H7	1–8 d	D+, S. Toxin produced in gut.	Water; ground beef, salami, and other meats; unpasteurized milk and juice; contaminated lettuce, sprouts; direct contact (eg, food handlers).
<i>Listeria monocytogenes</i>	9–32 h	D+, S. Invasive infection.	Milk, soft cheeses.
<i>Salmonella</i> spp.	12–36 h	D+. Invasive infection.	Meat; dairy; water; sprouts; direct contact (eg, food handlers).
<i>Shigella</i> spp.	1–7 d	D+. Invasive infection.	Water; fruits, vegetables; direct contact (eg, food handlers).
<i>Staphylococcus aureus</i>	1–6 h	V > D. Toxin preformed in food; heat-resistant.	Very common: meats; dairy; bakery foods; direct contact (eg, food handlers).
<i>Vibrio parahaemolyticus</i>	8–30 h	V, D+. Invasive and toxin produced in gut.	Shellfish; water.
<i>Yersinia enterocolitica</i>	3–7 d	D+. Invasive infection.	Water; meats; dairy.

^aV = vomiting; D = diarrhea; D+ = diarrhea with blood and/or fecal leukocytes; F = fever; S = systemic manifestations.

4. Antigen testing for *Giardia* can rule out this infection as a cause of diarrhea.

B. Other useful laboratory studies include CBC, electrolytes, glucose, BUN, and creatinine.

V. Treatment

A. Emergency and supportive measures

1. Replace fluid and electrolyte losses with intravenous saline or other crystalloid solutions (patients with mild illness may tolerate oral rehydration). Patients with hypotension may require large-volume intravenous fluid resuscitation (see p 16).
2. Antiemetic agents are acceptable for symptomatic treatment, but strong antidiarrheal agents such as Lomotil (diphenoxylate plus atropine) should

not be used in patients with suspected invasive bacterial infection (fever and bloody stools).

B. Specific drugs and antidotes. There are no specific antidotes.

1. In patients with invasive bacterial infection, antibiotics may be used once the stool culture reveals the specific bacteria responsible, although antibiotics do not always shorten the course of illness, and with *E coli* 0157:H7 they may increase the risk of hemolytic-uremic syndrome. Empiric treatment with ciprofloxacin is often initiated while awaiting culture results.
2. Pregnant women who have eaten *Listeria*-contaminated foods should be treated empirically, even if only mildly symptomatic, to prevent serious intrauterine infection. The antibiotic of choice is ampicillin, with gentamicin added for severe infection.

C. Decontamination. There is no role for gut decontamination.

D. Enhanced elimination. There is no role for enhanced removal procedures.

Altekruse SF et al: *Campylobacter jejuni*—an emerging foodborne pathogen. *Emerg Infect Dis* 1999;5(1):28–35. [PMID: 10081669] (*Campylobacter* is now the most commonly reported bacterial cause of food-borne infection in the United States. An increasing proportion are resistant to fluoroquinolones.)

Centers for Disease Control website on food-related illnesses: <http://www.cdc.gov/health/foodill.htm>

► FOOD POISONING: FISH AND SHELLFISH

Susan Kim, PharmD

A variety of toxins may produce illness after ingestion of fish or shellfish. The most common types of seafood-related toxins include **ciguatera**, **scombroid**, **neurotoxic shellfish poisoning**, **paralytic shellfish poisoning**, **tetrodotoxin**, and **domoic acid**. Shellfish-induced bacterial diarrhea is described on p 203.

I. Mechanism of toxicity. The mechanism varies with each toxin. The toxins are all heat-stable; therefore, cooking the seafood does not prevent illness.

- A. Ciguatera.** The toxin is produced by dinoflagellates, which are then consumed by reef fish. The mechanism of intoxication is uncertain, but may involve increased sodium permeability in sodium channels and stimulation of central or ganglionic cholinergic receptors.
- B. Diarrhetic shellfish poisoning** is caused by several identified toxins, all of which appear to be produced by marine dinoflagellates. Suspected toxins include okadaic acid, dinophysistoxins, and azaspiracid.
- C. Domoic acid** is produced by phytoplanktons, which are concentrated by filter-feeding fish and shellfish. The toxin is thought to bind to glutamate receptors, causing neuroexcitatory responses.
- D. Neurotoxic shellfish poisoning** is caused by ingestion of brevetoxins, which are produced by “red tide” dinoflagellates. The mechanism appears to involve stimulation of sodium channels, resulting in depolarization of nerve fibers.
- E. Palytoxin** is produced by dinoflagellates. It alters Na and K flux across cell membranes, causing depolarization and contraction of smooth, skeletal, and cardiac muscles. It is also a potent vasoconstrictor.
- F. Paralytic shellfish.** Dinoflagellates (“red tide”) produce saxitoxin, which is concentrated by filter-feeding clams and mussels. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.
- G. Scombroid.** Scombrototoxin is a mixture of histamine and other histamine-like compounds produced when histidine in fish tissue decomposes.
- H. Tetrodotoxin**, found in puffer fish, California newts, and some South American frogs, blocks the voltage-dependent sodium channel in nerve cell membranes.

- II. Toxic dose.** The concentration of toxin varies widely depending on geographic and seasonal factors. The amount of toxin necessary to produce symptoms is unknown. Saxitoxin is extremely potent; the estimated lethal dose in humans is 0.3–1 mg, and contaminated mussels may contain 15–20 mg.
- III. Clinical presentation.** The onset of symptoms and clinical manifestations vary with each toxin (Table II–27). In the majority of cases, the seafood appears normal with no adverse smell or taste (scombroid may have a peppery taste; palytoxin may be bitter).
- A. Ciguatera.** Intoxication produces vomiting and watery diarrhea 1–6 hours after ingestion, followed by headache, malaise, myalgias, paresthesias of the mouth and extremities, ataxia, blurred vision, photophobia, reversal of hot and cold sensation, extreme pruritus, hypotension, bradycardia, and rarely, seizures and respiratory arrest.
- B. Diarrhetic shellfish** poisoning causes nausea, vomiting, stomach cramps, and severe diarrhea. In animal studies, azaspiracid toxin caused damage to the liver, spleen, and small intestine.
- C. Domoic acid.** Symptoms begin from 15 minutes to 38 hours after ingestion and consist of gastroenteritis accompanied by unusual neurologic toxicity, including fasciculations, mutism, severe headache, hemiparesis, and myoclonus. Coma, seizures, hypotension, and profuse bronchial secretions have been reported with severe intoxication. Long-term sequelae include persistent severe anterograde memory loss (amnesic shellfish poisoning), motor neuropathy, and axonopathy.
- D. Neurotoxic shellfish.** Onset is within a few minutes to 3 hours. Gastroenteritis is accompanied by paresthesias of the mouth, face, and extremities; muscular weakness; seizures; and respiratory arrest.
- E. Clinical presentation of palytoxin** poisoning may initially mimic ciguatera. However, palytoxin produces greater morbidity and mortality, due to severe muscle spasms, rhabdomyolysis, hypertension, and acute respiratory failure.

TABLE II–27. SUMMARY OF FISH AND SHELLFISH INTOXICATIONS

Type	Onset	Common Sources	Syndrome
Ciguatera	1–6 h; milder cases may be delayed	Barracuda, red snapper, grouper	Gastroenteritis, hot and cold reversal, paresthesias, myalgias, weakness.
Diarrhetic shellfish	30 min to 2 h	Bivalve mollusks	Nausea, vomiting, diarrhea.
Domoic acid (amnesic shellfish poisoning)	Minutes to hours	Mussels, clams, anchovies	Gastroenteritis, headache, myoclonus, seizures, coma. Persistent neuropathy and memory impairment.
Neurotoxic shellfish	Minutes to 3 h	Bivalve shellfish, whelks (conchs)	Gastroenteritis, ataxia, paresthesias, seizures.
Palytoxin	Hours	Parrotfish, crabs, mackerel, sardines	Gastroenteritis; paresthesias; severe muscle spasms, rhabdomyolysis; seizures; respiratory distress; myocardial damage.
Paralytic shellfish	Within 30 min	Bivalve shellfish, “red tide”	Gastroenteritis, paresthesias, ataxia, respiratory paralysis.
Scombroid	Minutes to hours	Tuna, mahi mahi, bonito, mackerel	Gastroenteritis, flushed skin, urticaria, wheezing.
Tetrodotoxin	Within 30–40 min	Puffer fish (“fugu”), sunfish, porcupine fish, California newt	Vomiting, paresthesias, muscle twitching, diaphoresis, weakness, respiratory paralysis.

- F. Paralytic shellfish.** Vomiting, diarrhea, and facial paresthesias usually begin within 30 minutes of ingestion. Headache, myalgias, dysphagia, weakness, and ataxia have been reported. In serious cases respiratory arrest may occur after 1–12 hours.
- G. Scombroid.** Symptoms begin rapidly (minutes to 3 hours) after ingestion. Gastroenteritis, headache, and skin flushing are sometimes accompanied by urticaria and bronchospasm.
- H. Tetrodotoxin.** Symptoms occur within 30–40 minutes after ingestion and include vomiting, paresthesias, salivation, twitching, diaphoresis, weakness, and dysphagia. Hypotension, bradycardia, flaccid paralysis, and respiratory arrest may occur up to 6–24 hours after ingestion.
- IV. Diagnosis** depends on a history of ingestion and is more likely to be recognized when multiple victims present after consumption of a seafood meal. Scombroid may be confused with an allergic reaction because of the histamine-induced urticaria.
- A. Specific levels** are not generally available. However, when epidemic poisoning is suspected, state public health departments or the Centers for Disease Control may be able to analyze suspect food for toxins.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, arterial blood gases, ECG monitoring, and stool for bacterial culture.
- V. Treatment**
- A. Emergency and supportive measures.** Most cases are mild and self-limited and require no specific treatment. However, because of the risk of respiratory arrest, all patients should be observed for several hours (except for patients with diarrhetic shellfish poisoning).
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Replace fluid and electrolyte losses from gastroenteritis with intravenous crystalloid fluids.
- B. Specific drugs and antidotes**
1. **Scombroid** intoxication can be treated symptomatically with antihistamines, including diphenhydramine (see p 436) and cimetidine, 300 mg IV. Rarely, bronchodilators may also be required.
 2. **Ciguatera.** There are anecdotal reports of successful treatment with intravenous mannitol, 0.5–1 g/kg infused IV over 30 minutes. However, a recent randomized study showed no difference in outcome between mannitol and saline therapy. Gabapentin (400 mg TID) has also been reported to relieve symptoms.
- C. Decontamination** (see p 46)
1. **Prehospital.** Administer activated charcoal if available.
 2. **Hospital.** Administer activated charcoal. Consider gastric lavage if ingestion occurred within the preceding hour.
- D. Enhanced elimination.** There is no role for these procedures.

Schnorf H et al: Ciguatera fish poisoning: a double-blind randomized trial of mannitol therapy. *Neurology* 2002;58(6):873–880. [PMID: 11914401] (No difference in symptom relief after 24 hours between a single dose of mannitol versus saline.)

► FORMALDEHYDE

John Balmes, MD

Formaldehyde is a gas with a pungent odor commonly used in the processing of paper, fabrics, and wood products and for the production of urea foam insulation. Low-level formaldehyde exposure has been found in stores selling clothing treated with formaldehyde-containing crease-resistant resins, in mobile homes, and in tightly

enclosed rooms built with large quantities of formaldehyde-containing products used in construction materials. Formaldehyde aqueous solution (formalin) is used in varying concentrations (usually 37%) as a disinfectant and tissue fixative. Stabilized formalin may also contain 6–15% methanol.

I. Mechanism of toxicity

- A. Formaldehyde causes precipitation of proteins and will cause coagulation necrosis of exposed tissue. The gas is highly water soluble and when inhaled produces immediate local irritation of the upper respiratory tract and has been reported to cause spasm and edema of the larynx.
- B. Metabolism of formaldehyde produces formic acid, which may accumulate and produce metabolic acidosis if sufficient formaldehyde was ingested.
- C. Formaldehyde is a known animal and suspected human carcinogen.

II. Toxic dose

- A. **Inhalation.** The recommended workplace ceiling limit (ACGIH TLV-C) is 0.3 ppm (0.37 mg/m³), which should not be exceeded at any time. The air level considered immediately dangerous to life or health (IDLH) is 20 ppm.
- B. **Ingestion** of as little as 30 mL of 37% formaldehyde solution has been reported to have caused death in an adult.

III. Clinical presentation

- A. **Formaldehyde gas** exposure produces irritation of the eyes, and inhalation can produce cough, wheezing, and noncardiogenic pulmonary edema.
- B. **Ingestion** of formaldehyde solutions may cause severe corrosive esophageal and gastric injury, depending on the concentration. Lethargy and coma have been reported. Metabolic (anion gap) acidosis may be caused by formic acid accumulation from metabolism of formaldehyde or methanol.
- C. Hemolysis has occurred when formalin was accidentally introduced into the blood through contaminated hemodialysis equipment.

IV. Diagnosis

is based on a history of exposure and evidence of mucous membrane, respiratory, or gastrointestinal tract irritation.

A. Specific levels

- 1. Plasma formaldehyde levels are not useful, but formate levels may indicate severity of intoxication.
- 2. Methanol (see p 260) and formate levels may be helpful in cases of intoxication by formalin solutions containing methanol.

B. Other useful laboratory studies

include electrolytes, glucose, BUN, creatinine, and osmolar gap (see p 32).

V. Treatment

A. Emergency and supportive measures

- 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
- 2. **Inhalation.** Treat bronchospasm (see p 8) and pulmonary edema (p 7) if they occur. Administer supplemental oxygen, and observe for at least 4–6 hours.
- 3. **Ingestion**
 - a. Treat coma (see p 19) and shock (p 16) if they occur.
 - b. Administer intravenous saline or other crystalloids to replace fluid losses caused by gastroenteritis. Avoid fluid overload in patients with inhalation exposure because of the risk of pulmonary edema.
 - c. Treat metabolic acidosis with sodium bicarbonate (see p 33).

B. Specific drugs and antidotes

- 1. If a **methanol**-containing solution has been ingested, then evaluate and treat with **ethanol** and **folic acid** as for methanol poisoning (see p 260).
- 2. **Formate** intoxication caused by formaldehyde alone should be treated with **folic acid** (see p 447), but ethanol infusion is not effective.
- C. **Decontamination** (see p 46). Rescuers should wear self-contained breathing apparatus and appropriate chemical-protective clothing if handling a heavily contaminated patient.
 - 1. **Inhalation.** Remove victims from exposure and give supplemental oxygen if available.

2. **Skin and eyes.** Remove contaminated clothing and wash exposed skin with soap and water. Irrigate exposed eyes with copious tepid water or saline; perform fluorescein examination to rule out corneal injury if pain and lacrimation persist.
3. **Ingestion** (see p 48). Depending on the concentration of solution and patient symptoms, consider endoscopy to rule out esophageal or gastric injury.
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of corrosive injury.
 - b. **Hospital.** Perform gastric lavage. Administer activated charcoal (although note that charcoal may obscure view during endoscopy).
- D. **Enhanced elimination**
 1. **Hemodialysis** is effective in removing methanol and formate and in correcting severe metabolic acidosis. Indications for hemodialysis include severe acidosis or osmolar gap (see p 32) greater than 10 mOsm/L.
 2. **Alkalinization** of the urine helps promote excretion of formate.

Feron VJ: Health risks associated with inhaled nasal toxicants. *Crit Rev Toxicol* 2001;31(3):313–347. [PMID: 11405443] (Review.)

► FREONS AND HALONS

Dennis Shusterman, MD, MPH

Freons (fluorocarbons and chlorofluorocarbons [CFCs]) have historically been widely used as aerosol propellants, in refrigeration units, and as degreasing agents. Under provisions of the Montreal Protocol of 1987, the use of CFCs is being phased out to avoid further depletion of stratospheric ozone. Nevertheless, freons remain in older refrigeration and air conditioning systems, and illicit import of freons is common. Most freons are gases at room temperature, but some are liquids (freons 11, 21, 113, and 114) and may be ingested. Some fire extinguishers contain closely related compounds known as **halons**, which contain bromine, fluorine, and (variably) chlorine.

I. Mechanism of toxicity

- A. Freons are mild CNS depressants. They may also displace oxygen from the air, causing hypoxemia. Freons are well absorbed by inhalation or ingestion and are usually rapidly excreted in the breath within 15–60 minutes.
- B. As with chlorinated hydrocarbons, freons may potentiate cardiac arrhythmias by increasing the sensitivity of the myocardium to the effects of catecholamines.
- C. Direct freezing of the skin, with frostbite, may occur if the skin is exposed to rapidly expanding gas as it escapes from a pressurized tank.
- D. Freons and halons may produce potent irritant gases and vapors (eg, phosphene, hydrochloric acid, hydrofluoric acid, and carbonyl fluoride) when heated to high temperatures, as might happen in a fire or if a refrigeration line is cut by a welding torch or electric arc.
- E. Some agents are hepatotoxic after large acute or chronic exposure.

II. Toxic dose

- A. **Inhalation.** The toxic air level is quite variable, depending on the specific agent (see Table IV–4, p 532). Freon 21 (dichlorofluoromethane; TLV 10 ppm [42 mg/m³]) is much more toxic than freons 12 and 22 (TLV 1000 ppm). In general, anesthetic or CNS-depressant doses require fairly large air concentrations, which can also displace oxygen, leading to asphyxia. The air level of dichloromonofluoromethane considered immediately dangerous to life or health (IDLH) is 5000. Other TLV and IDLH values can be found in Table IV–4 (p 532).

B. Ingestion. The toxic dose by ingestion is not known.

III. Clinical presentation

A. Skin or mucous membrane exposure may result in skin defatting and erythema. Frostbite may occur after exposure to rapidly expanding compressed gas.

B. Systemic effects of moderate exposure include headache, nausea and vomiting, confusion, and drunkenness. More severe intoxication may result in coma or respiratory arrest. Ventricular arrhythmias may occur even with moderate exposures. A number of deaths, presumably caused by ventricular fibrillation, have been reported after freon abuse by “sniffing” or “huffing” freon products from plastic bags. Hepatic injury may occur.

IV. Diagnosis is based on a history of exposure and clinical presentation. Many chlorinated and aromatic hydrocarbon solvents may cause identical symptoms.

A. Specific levels. Expired-breath monitoring is possible, and blood levels may be obtained to document exposure, but these are not useful in emergency clinical management.

B. Other useful laboratory studies include arterial blood gases or oximetry, ECG monitoring, and liver enzymes.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19) and arrhythmias (pp 10–15) if they occur. Avoid epinephrine or other sympathomimetic amines that may precipitate ventricular arrhythmias. Tachyarrhythmias caused by increased myocardial sensitivity may be treated with **propranolol** (see p 496), 1–2 mg IV, or **esmolol** (see p 443), 0.025–0.1 mg/kg/min IV.
3. Monitor the ECG for 4–6 hours.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Inhalation.** Remove victim from exposure, and give supplemental oxygen if available.
2. **Ingestion** (see p 48)
 - a. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting because of rapid absorption and the risk of abrupt onset of CNS depression.
 - b. **Hospital.** Administer activated charcoal, although the efficacy of charcoal is unknown. Perform gastric lavage only if the ingestion was very large and recent (less than 30 minutes).

D. Enhanced elimination. There is no documented efficacy for diuresis, hemodialysis, hemoperfusion, or repeat-dose charcoal.

Kurbat RS, Pollack CV Jr: Facial injury and airway threat from inhalant abuse: a case report. *J Emerg Med* 1998;16(2):167–169. [PMID: 9543396] (Facial frostbite is another potential complication of fluorinated hydrocarbon abuse.)

► GAMMA-HYDROXYBUTYRATE (GHB)

Jo Ellen Dyer, PharmD

Gamma-hydroxybutyrate (GHB) was originally investigated as an anesthetic agent during the 1960s but abandoned because of side effects including myoclonus and emergence delirium. In 2002 it was approved by the FDA as a treatment for cataplexy symptoms in patients with narcolepsy. For abuse purposes GHB is readily available through the illicit drug market, and can be made in home labs using recipes posted on the Internet. As a result of increasing abuse, GHB without a legitimate prescription is regulated as a Schedule I substance. Chemical precursors that are converted to GHB in the body, including **gamma-butyrolactone (GBL)** and **1,4-butane-**

diol (1,4-BD), are also regulated as Schedule I analogs (when intended for human consumption). These chemicals are often sold under constantly changing product names with intentionally obscure chemical synonyms (Table II–28), and, to avoid legal consequences of an analog intended for human consumption, they may be sold as a cleaner, paint stripper, nail polish remover, or solvent, labeled “not for ingestion.”

GHB has been promoted as a growth hormone releaser, muscle builder, diet aid, soporific, euphoriant, hallucinogen, antidepressant, alcohol substitute, and enhancer of sexual potency. GHB use in dance clubs and at rave parties commonly involves ingestion along with ethanol and other drugs. GHB has also become known as a

“date rape” drug, because it can produce a rapid incapacitation or loss of consciousness, facilitating sexual assault.

I. Mechanism of toxicity

- A. **GHB** is a structural analog of the neurotransmitter gamma-aminobutyric acid (GABA) with agonist activity at both GABA(B) and GHB receptors. It readily crosses the blood-brain barrier, resulting in general anesthesia and respiratory depression. Death results from injury secondary to abrupt loss of consciousness, apnea, pulmonary edema, or pulmonary aspiration of gastric contents. Fatal potentiation of GHB's depressant effects has occurred with ethanol and other depressant drugs.
- B. **Gamma-butyrolactone (GBL)**, a solvent now regulated by the DEA as a List I Chemical, can be chemically converted by sodium hydroxide to GHB. In addition, GBL is rapidly converted in the body by peripheral lactonases to GHB within minutes.
- C. **1,4-Butanediol (1,4-BD)**, an intermediate for chemical synthesis, is readily available through chemical suppliers. 1,4-BD is converted *in vivo* by alcohol dehydrogenase to gamma-hydroxybutyraldehyde, then by aldehyde dehydrogenase to GHB.
- D. **Pharmacokinetics.** Onset of CNS depressant effects begins within 10–15 minutes after oral ingestion of GHB and 2–8 minutes after intravenous injection. Peak levels occur within 25–45 minutes, depending on the dose. A recent meal may reduce systemic bioavailability by 37% compared to the fasting state. The duration of effect is 1–2.5 hours after anesthetic doses of 50–60 mg/kg and about 2.5 hours in nonintubated accidental overdoses seen in the emergency department (range 15 minutes–5 hours). The rate of elimination of GHB is saturable. Plasma blood levels of GHB are undetectable within 4–6 hours after therapeutic doses. The volume of distribution (Vd) is variable due to saturable absorption and elimination. GHB is not protein bound.

II. Toxic dose

- A. **GHB.** Response to low oral doses of GHB is unpredictable, with variability between patients and in the same patient. Narcolepsy studies with 30 mg/kg have reported effects including abrupt onset of sleep, enuresis, hallucinations, and myoclonic movements. Anesthetic studies reported unconsciousness with 50 mg/kg and deep coma with 60 mg/kg. Fasting, ethanol, and other depressants enhance the effects of GHB.
- B. **GBL**, a nonionized molecule, has greater bioavailability than GHB when given orally in the same doses. A dose of 1.5 g produced sleep lasting 1 hour.
- C. **1,4-BD** is equipotent to GHB, although in the presence of ethanol, competition for the metabolic enzyme alcohol dehydrogenase may delay or decrease the peak effect.

III. Clinical presentation. Patients with acute GHB overdose commonly present with coma, bradycardia, and myoclonic movements.

- A. **Soporific effects and euphoria** usually occur within 15 minutes of an oral dose; unconsciousness and deep coma may follow within 30–40 minutes. When GHB is ingested alone, the duration of coma is usually short with recovery within 2 to 4 hours and complete resolution of symptoms within 8 hours.
- B. **Delirium and tonic-clonic seizures** are possible. Bradypnea with increased tidal volume is frequently seen. Cheyne-Stokes respiration and loss of airway-protective reflexes occur. Vomiting is seen in 30–50% of cases, and incontinence may occur. Stimulation may cause tachycardia and mild hypertension, but bradycardia is more common.
- C. **Alkaline corrosive burns** result from misuse of the home manufacture kits: a dangerously basic solution is produced when excess base is added, the reaction is incomplete, or there is inadequate back titration with acid. (The solution can also be acidic from excessive back titration.)
- D. Frequent use of GHB in high doses may produce tolerance and dependence. A **withdrawal syndrome** has been reported when chronic use is discontin-

ued. Symptoms include tremor, paranoia, agitation, confusion, delirium, visual and auditory hallucinations, tachycardia, and hypertension. Rhabdomyolysis, myoclonus, and death have occurred.

E. See also the discussion of **drug-facilitated assault**, p 63.

IV. **Diagnosis** is usually suspected clinically in the patient who presents with abrupt onset of coma and recovers rapidly within a few hours.

A. **Specific levels.** Laboratory tests for GHB levels are not readily available but can be obtained from a few national reference laboratories. Serum levels greater than 50 mg/L are associated with loss of consciousness, and levels over 260 mg/L usually produce unresponsive coma. In a small series of accidental overdoses, awakening occurred as levels fell into the 75–150 mg/L range. GBL and 1,4-BD are rapidly converted in vivo to GHB. The duration of detection of GHB in blood and urine is short (6 and 12 hours, respectively, after therapeutic doses).

B. **Other useful laboratory studies** include glucose, electrolytes, and arterial blood gases or oximetry. Consider urine toxicology screening and blood ethanol to rule out other common drugs of abuse that may enhance or prolong the course of poisoning.

V. Treatment

A. Emergency and supportive measures

1. Protect the airway and assist ventilation if needed. Note that patients who require intubation are often awake and extubated within a few hours.

2. Treat coma (see p 19), seizures (p 22), bradycardia (p 10), and corrosive burns (p 157) if they occur.

3. Evaluate for and treat drug-facilitated assault (see p 63).

B. **Specific drugs and antidotes.** There are no specific antidotes available. Flumazenil and naloxone are not clinically effective. GHB withdrawal syndrome is managed with benzodiazepine (see p 415) sedation similar to other depressant withdrawal syndromes. Large doses may be needed. Withdrawal refractory to benzodiazepines is not uncommon and may benefit from the addition of barbiturates (p 486) or propofol (p 494).

C. Decontamination

1. **Prehospital.** Do not induce vomiting, because of the risk of rapid loss of consciousness and loss of airway-protective reflexes, which may lead to pulmonary aspiration. Consider activated charcoal (see p 51) if available soon after a large ingestion.

2. **Hospital.** The small doses of GHB usually ingested are rapidly absorbed, and gastric lavage and activated charcoal are of doubtful benefit and may increase the risk of pulmonary aspiration. Consider activated charcoal administration for recent, large ingestions or when significant co-ingestion is suspected.

D. **Enhanced elimination.** There is no role for enhanced removal procedures such as dialysis or hemoperfusion.

Dyer JE et al: Gamma hydroxybutyrate withdrawal syndrome. *Ann Emerg Med* 2001;37(2):147–153. [PMID: 111 74 231] (Description of severe GHB withdrawal syndrome.)

► GASES, IRRITANT

John Balmes, MD

A vast number of compounds produce irritant effects when inhaled in their gaseous form. The most common source of exposure to irritant gases is in industry, but significant exposures may occur in a variety of circumstances, such as after mixing cleaning agents at home, with smoke inhalation in structural fires, or after highway tanker spills.

- I. **Mechanism of toxicity.** Irritant gases are often divided into two major groups based on their water solubility (Table II–29).
 - A. **Highly soluble gases** (eg, ammonia and chlorine) are readily adsorbed by the upper respiratory tract and rapidly produce their primary effects on moist mucous membranes in the eyes, nose, and throat.
 - B. **Less soluble gases** (eg, phosgene and nitrogen dioxide) are not rapidly adsorbed by the upper respiratory tract and can be inhaled deeply into the lower respiratory tract to produce delayed-onset pulmonary toxicity.
- II. **Toxic dose.** The toxic dose varies depending on the properties of the gas. Table II–29 illustrates the workplace exposure limits (TLV-TWA) and the levels immediately dangerous to life or health (IDLH) for several common irritant gases.
- III. **Clinical presentation.** All of these gases may produce irritant effects to the upper and/or lower respiratory tract, but warning properties and the onset and location of primary symptoms depend largely on the water solubility of the gas and the concentration of exposure.
 - A. **Highly soluble gases.** Because of the good warning properties (upper respiratory tract irritation) of highly soluble gases, voluntary prolonged exposure to even low concentrations is unlikely.
 - 1. Low-level exposure causes rapid onset of mucous membrane and upper respiratory tract irritation; conjunctivitis, rhinitis, skin erythema and burns, sore throat, cough, wheezing, and hoarseness are common.
 - 2. With high-level exposure, laryngeal edema, tracheobronchitis, and abrupt airway obstruction may occur. Irritation of the lower respiratory tract and lung parenchyma causes tracheobronchial mucosal sloughing, chemical pneumonitis, and noncardiogenic pulmonary edema.

TABLE II–29. CHARACTERISTICS OF SOME COMMON IRRITANT TOXIC GASES

Gas	TLV ^a (ppm)	IDLH ^b (ppm)
High water solubility		
Ammonia	25	300
Formaldehyde	0.3 (C)	20
Hydrogen chloride	5 (C)	50
Hydrogen fluoride	3 (C)	30
Nitric acid	2	25
Sulfur dioxide	2	100
Moderate water solubility		
Acrolein	0.1	5
Chlorine	0.5	10
Fluorine	1	25
Low water solubility		
Nitric oxide	25	100
Nitrogen dioxide	3	50
Ozone	0.2 ^c	5
Phosgene	0.1	2

^aTLV = Threshold limit value, ACGIH recommended exposure limit as an 8-hour time-weighted average for a 40-hour workweek (TLV-TWA); C = ceiling level (see p 528).

^bIDLH = Air level considered immediately dangerous to life or health, defined as the maximum air concentration from which one could reasonably escape within 30 minutes without any escape-impairing symptoms or any irreversible health effects.

^cFor exposure of no more than 2 hours.

- B. Less soluble gases.** Because of poor warning properties owing to minimal upper respiratory tract effects, prolonged exposure to moderate levels of these gases often occurs; therefore, chemical pneumonitis and pulmonary edema are more common. The onset of pulmonary edema may be delayed up to 12–24 hours or even longer.
- C. Sequelae.** Although most patients who suffer toxic inhalation injury will recover without any permanent impairment, bronchiectasis, bronchiolitis obliterans, persistent asthma, and pulmonary fibrosis can occur.
- IV. Diagnosis** is based on a history of exposure and the presence of typical irritant upper- or lower-respiratory effects. Arterial blood gases and chest x-ray may reveal early evidence of chemical pneumonitis or pulmonary edema. Whereas highly soluble gases have good warning properties and the diagnosis is not difficult, less soluble gases may produce minimal symptoms shortly after exposure; therefore, a high index of suspicion and repeated examinations are required.
- A. Specific levels.** There are no specific blood or serum levels available.
- B. Other useful laboratory studies** include arterial blood gases or oximetry, chest x-ray, spirometry, or peak expiratory flow measurement.
- V. Treatment**
- A. Emergency and supportive measures**
1. Immediately assess the airway; hoarseness or stridor suggests laryngeal edema, which necessitates direct laryngoscopy and endotracheal intubation if swelling is present (see p 4). Assist ventilation if necessary (p 6).
 2. Give supplemental oxygen, and treat bronchospasm with aerosolized bronchodilators (see p 8).
 3. Monitor arterial blood gases or oximetry, chest x-ray, and pulmonary function. Treat pulmonary edema if it occurs (see p 7).
 4. For victims of smoke inhalation, consider the possibility of concurrent intoxication by carbon monoxide (see p 151) or cyanide (p 177).
- B. Specific drugs and antidotes.** There is no specific antidote for any of these gases.
- C. Decontamination** (see p 46). Remove victim from exposure and give supplemental oxygen if available. Rescuers should take care to avoid personal exposure; in most cases, self-contained breathing apparatus should be worn.
- D. Enhanced elimination.** There is no role for enhanced elimination.

Wang H et al: Cigarette smoke inhibits human bronchial epithelial cell repair processes. *Am J Respir Cell Mol Biol* 2001;25(6):772–779. [PMID: 11726404] (Cigarette smoke contains numerous toxic compounds, including acetaldehyde and acrolein.)

► HERBAL AND ALTERNATIVE PRODUCTS

Christine A. Haller, MD

The use of herbal medicines, dietary supplements, and other alternative products has risen sharply since passage of the Dietary Supplement Health and Education Act (DSHEA) in 1994. In contrast to requirements for prescription or nonprescription drugs, FDA approval is not required prior to marketing of these products. Premarket testing for safety and efficacy is not mandated, and adherence to good manufacturing practices and quality control standards is not enforced. Consumers often mistakenly believe that these “natural” products are free of harm, and may unknowingly be at risk of illness from the products and herb-drug, and herb-disease interactions, particularly with “polysupplement” use. Table II–30 lists common uses of selected products that are available as herbal remedies, dietary supplements, or other alternative uses and their potential toxicities.

I. Mechanism of Toxicity

- A.** A number of poisonings related to herbal preparations are due to **contaminants** such as cadmium, lead, arsenic, mercury, or pharmaceutical **adulter-**

TABLE II-30. SELECTED DIETARY SUPPLEMENTS AND ALTERNATIVE REMEDIES^a

Product	Source or Active Ingredient	Common or Purported Use	Clinical Effects and Potential Toxicity
Androstenedione	Sex steroid precursor	Increase muscle size and strength	Virilization in women, increased estrogen in men.
Anabolic steroids	Methandrostenolone, oxandrolone, testolactone, many other steroid derivatives	Body building	Virilization; feminization; cholestatic hepatitis; aggressiveness, mania, or psychosis; hypertension; acne; hyperlipidemia; immune suppression.
Azarcon (Greta)	Lead salts	Hispanic folk remedy for abdominal pain, colic	Lead poisoning (see p 238).
Bitter orange	<i>Citrus aurantium</i> (source of synephrine)	Weight loss, athletic enhancement	Synephrine: alpha-adrenergic agonist (see p 320). May cause vasoconstriction, hypertension.
Bufotoxin	Bufotenine (toad venom); "love stone"; Chan su	Purported aphrodisiac; hallucinogen	Cardiac glycosides (see p 155).
Cascara sagrada	<i>Rhamnus purshiana</i>	Cathartic in some diet aids	Abdominal cramps, diarrhea; fluid and electrolyte loss.
Chitosan	Derived from marine exoskeletons	Weight loss	Dyspepsia; oily stools; shellfish hypersensitivity reaction.
Chondroitin sulfate	Shark or bovine cartilage, or synthetic	Osteoarthritis	Possible anticoagulant activity.
Chromium	Chromium picolinate	Body building; athletic performance enhancement	Gastrointestinal irritation; niacin-like flushing reaction with picolinate salt.
Comfrey	<i>Symphytum officinale</i>	Anti-inflammatory; gastritis; diarrhea	Hepatic veno-occlusive disease; possible teratogen/carcinogen. (Note: many other plants also contain hepatotoxic pyrrolizidine alkaloids—see Table II-46).
Creatine	Creatine monohydrate; creatine monophosphate	Athletic performance enhancement	Gastrointestinal irritation.
DHEA	Dihydroepiandrosterone (an adrenal steroid)	Anticancer; anti-aging	Possible androgenic effects.
Echinacea	<i>Echinacea angustifolia</i> ; <i>Echinacea pallida</i> ; <i>Echinacea purpurea</i>	Immune stimulation	Allergic dermatitis; dizziness.
Feverfew	<i>Tanacetum parthenium</i>	Migraine	Antiprostaglandin; antiplatelet effects.
Garlic	<i>Allium sativum</i>	Hyperlipidemia; hypertension	Rash; gastrointestinal irritation and acid reflux; asthma.
Ginkgo	Extract of <i>Ginkgo biloba</i>	Memory impairment, tinnitus, peripheral vascular disease	Gastrointestinal irritation; antiplatelet effects.
Ginseng	<i>Panax ginseng</i> ; <i>Panax quinquefolium</i>	Fatigue/stress; immune stimulation; many ailments	Decreases serum glucose; increases cortisol. <i>Ginseng abuse syndrome</i> : nervousness; insomnia; gastrointestinal distress.
Glucosamine	Marine exoskeletons, or synthetic	Osteoarthritis	Possibly decreased insulin production.

(continued)

TABLE II-30. SELECTED DIETARY SUPPLEMENTS AND ALTERNATIVE REMEDIES^a (CONTINUED)

Product	Source or Active Ingredient	Common or Purported Use	Clinical Effects Potential Toxicity
Goldenseal	<i>Hydrastis canadensis</i>	Dyspepsia; postpartum bleeding; drug test adulterant	Nausea; vomiting; diarrhea; paresthesia; seizures; hypo- or hypertension.
Grape seed extract	Procyanidins	Circulatory disorders, antioxidant	None known.
Guarana	Caffeine	Athletic performance enhancement; appetite suppressant	Tachycardia, tremor; vomiting (See Caffeine, p 142).
Jin bu huan	<i>1</i> -Tetrahydropalmatine	Chinese traditional medicine	Acute CNS depression and bradycardia; chronic hepatitis.
Kava	<i>Piper methysticum</i>	Anxiety, insomnia	Drowsiness; hepatitis, cirrhosis and liver failure; habituation and reversible skin rash.
Ma huang	Ephedrine (various <i>Ephedra</i> spp.)	Stimulant; athletic performance enhancement; appetite suppressant	Insomnia; hypertension, tachycardia; psychosis, seizures (see Caffeine, p 142).
Melatonin	Pineal gland	Sleep aid	Sedation; headache; loss of libido.
Milk thistle	<i>Silybum marianum</i>	Toxic hepatitis and other liver diseases	Mild GI distress; possible allergic reaction.
Saw palmetto	Extract of saw palmetto berry	Benign prostatic hypertrophy	Anti androgenic.
Senna	<i>Cassia angustifolia</i> ; <i>Cassia acutifolia</i>	Weight loss; laxative	Watery diarrhea; abdominal cramps; fluid and electrolyte loss.
Shark cartilage	Pacific Ocean shark- a <i>Squalus acanthius</i>	Cancer, arthritis	Bad taste; hepatitis; hypercalcemia.
Spirulina	Some blue-green algae	Body building	Niacin-like flushing reaction (see p 366).
St. John's wort	<i>Hypericum perforatum</i>	Antidepressant	Possible mild MAO inhibition (see p 269); photosensitivity; P-269 enzyme inducer.
Tea tree oil	<i>Melaleuca alternifolia</i>	Topical antifungal; vaginitis; acne	Sedation; ataxia; contact dermatitis.
Tryptophan	Essential amino acid	Insomnia, depression	"Eosinophilia-myalgia syndrome" was reported in 1989, possibly due to contaminants in production of tryptophan. Similar contaminants have been found in 5-hydroxy-L-tryptophan.
Valerian root	<i>Valeriana officianalis</i> ; <i>Valeriana edulis</i>	Sleep aid	Sedation; vomiting.
Vanadium	Vanadyl sulfate; ammonium vanadyl tartrate	Body building	Intestinal cramps, diarrhea; black stools.
Yohimbine	<i>Corynanthe yohimbe</i>	Stimulant; purported aphrodisiac	Hallucinations; MAO inhibition; hypertension; irritability; gastrointestinal irritation.
Zinc	Zinc gluconate lozenges	Flu/cold symptoms	Nausea; mouth/throat irritation.

^aMost of these products are legally considered neither food nor drugs and, therefore, are not regulated by the FDA (Dietary Supplement Health and Education Act, 1994). Toxicity may be related to the active ingredient(s) or to impurities, contaminants, or adulterants in the product. See also Caffeine (p 142), Essential Oils (p 147), Salicylates (p 331), and Vitamins (p 366).

ants such as diazepam, acetaminophen, phenylbutazone, and prednisone. An epidemic of "eosinophilia-myalgia syndrome" appears to have been caused by contaminants associated with mass production of the amino acid tryptophan.

- B. Some herbs are intrinsically toxic, and poisoning may occur as a result of **misidentification**, mislabeling, or improper processing of plant materials.
- C. **Herb-drug interactions.** Herbal products may potentiate or diminish the effects of drugs with narrow therapeutic margins. Garlic, ginseng, ginger, and ginkgo biloba appear to have anticoagulant effects and should not be used concomitantly with warfarin, aspirin, or other antiplatelet therapies. St. John's wort has been shown to have several clinically significant pharmacokinetic interactions with substrates for *p*-glycoprotein and the CY-P-450 system, resulting in decreased plasma levels of drugs such as indinavir, cyclosporine, digoxin, and oral contraceptives.

III. **Clinical presentation** will depend on the toxic constituent of the herbal product, and may be acute in onset (for example, with the cardiac stimulant effects of ephedra or guarana) or delayed (as with Chinese herbal nephropathy due to *Aristolochia fangchi*). Allergic reactions to botanical products may manifest with skin rash, including urticaria, bronchospasm, or even anaphylaxis.

IV. **Diagnosis** is based on a history of use of alternative products and exclusion of other medical/toxicological causes. Identification of an unknown herb may be facilitated by consulting with a local Chinese herbalist, acupuncturist, or naturopathic practitioner. In some cases, chemical analysis of the product may confirm the presence of the suspected causative constituent or contaminant.

- A. **Specific levels.** Quantitative levels are not available for most alternative medicine toxins. Ephedrine can be measured in blood and urine of people taking *Ma huang*.
- B. **Laboratory studies.** Serum electrolytes including glucose, BUN, creatinine, liver transaminases, and prothrombin time are useful in cases of suspected organ toxicity due to alternative therapies.

V. Treatment

- A. **Emergency and supportive measures.** Toxic effects of herbal medicines should be managed with the same approach taken with other ingestions.
 - 1. Replace fluid losses due to diarrhea or vomiting with intravenous crystalloid (see p 16).
 - 2. Treat hypertension (see p 16), tachycardia (p 12), or arrhythmias (pp 10–15) if they occur.
 - 3. Treat anxiety, agitation, or seizures (see p 22) due to stimulant herbs with intravenous benzodiazepines (p 415).
 - 4. Maintain an open airway and assist ventilation if necessary in cases of CNS depression or coma related to sedative herb use.
- B. **Specific drugs and antidotes.** There are no specific antidotes for toxicity related to herbal and alternative products.
- C. **Decontamination** (see p 47)
 - 1. **Prehospital.** Administer activated charcoal, if available.
 - 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if charcoal can be given promptly.
- D. **Enhanced elimination.** The effectiveness of these procedures in removing herbal and alternative medicine toxins has not been studied.

[PMID: 11777363] (A detailed analysis of the available scientific evidence on six popular herbal products, including information on efficacy, dosage, and safety.)

► **HYDROCARBONS**

Collin S. Goto, MD

Hydrocarbons are widely used as solvents, degreasers, fuels, and lubricants. Hydrocarbons include organic compounds derived from petroleum distillation as well as many other sources, including plant oils, animal fats, and coal. Subcategories of hydrocarbons include aliphatic (saturated carbon structure), aromatic (containing one or more benzene rings), halogenated (containing chlorine, bromine, or fluoride atoms), alcohols and glycols, ethers, ketones, carboxylic acids, and many others. This chapter emphasizes toxicity caused by common household hydrocarbons. See specific chemicals elsewhere in Section II and in Section IV, Table IV–4 (p 532).

- I. **Mechanism of toxicity.** Hydrocarbons may cause direct injury to the lung after pulmonary aspiration or systemic intoxication after ingestion, inhalation, or skin absorption (Table II–31). Many hydrocarbons are also irritating to the eyes and skin.
- A. **Pulmonary aspiration.** Chemical pneumonitis is caused by direct tissue damage and disruption of surfactant. Aspiration risk is greatest for hydrocarbons with low viscosity and low surface tension (eg, petroleum naphtha, gasoline, turpentine).
- B. **Ingestion**
 - 1. **Aliphatic hydrocarbons** and **simple petroleum distillates** such as lighter fluid, kerosene, furniture polish, and gasoline are poorly absorbed from the gastrointestinal tract and do not pose a significant risk of systemic toxicity after ingestion, as long as they are not aspirated.
 - 2. In contrast, many **aromatic** and **halogenated hydrocarbons, alcohols, ethers, ketones**, and other **substituted or complex hydrocarbons** are capable of causing serious systemic toxicity, such as coma, seizures, and cardiac arrhythmias.
- C. **Inhalation** of hydrocarbon vapors in an enclosed space may cause intoxication as a result of systemic absorption or by displacing oxygen from the atmosphere.
- D. **Injection** of hydrocarbons into skin, subcutaneous tissue, or muscle may cause a severe local inflammatory reaction and liquefaction necrosis.
- E. **Skin and eye contact** can cause local irritation. **Dermal** absorption can be significant for some agents but is insignificant for most of the simple, aliphatic compounds.

TABLE II–31. RISK OF TOXICITY FROM HYDROCARBON INGESTION

Common Compounds	Risk of Systemic Toxicity after Ingestion	Risk of Chemical Aspiration Pneumonia	Treatment
No systemic toxicity, high viscosity Petrolatum jelly, motor oil	Low	Low	None.
No systemic toxicity, low viscosity Gasoline, kerosene, petroleum naphtha, mineral seal oil, petroleum ether	Low	High	Observe for pneumonia; do <i>not</i> empty stomach.
Unknown or uncertain systemic toxicity Turpentine, pine oil	Uncertain	High	Observe for pneumonia; do <i>not</i> empty stomach if ingestion is < 2 mL/kg.
Systemic toxins Camphor, phenol, halogenated, or aromatic compounds	High	High	Observe for pneumonia; perform gastric lavage or give activated charcoal or do both.

- II. Toxic dose.** The toxic dose is variable depending on the agent involved and whether it is aspirated, ingested, injected, or inhaled.
- A. Pulmonary aspiration** of as little as a few milliliters may produce chemical pneumonitis.
 - B. Ingestion** of as little as 10–20 mL of some systemic toxins, such as camphor or carbon tetrachloride, may cause serious or fatal poisoning.
 - C. For recommended inhalation exposure limits** for common hydrocarbons, see Table IV–4, p 532.
 - D. Injection** of less than 1 mL can cause significant local tissue inflammation.
 - E. Dermal absorption** is insignificant for most simple aliphatic compounds but may occur with other agents.
- III. Clinical presentation**
- A. Pulmonary aspiration** usually causes immediate onset of coughing, gagging, or choking. This may progress within minutes or hours to tachypnea, grunting, wheezing, and severe chemical pneumonitis. Death may ensue from secondary bacterial infection and other respiratory complications.
 - B. Ingestion** often causes abrupt nausea and vomiting, occasionally with hemorrhagic gastroenteritis. Some compounds may be absorbed and produce systemic toxicity.
 - C. Systemic toxicity** caused by hydrocarbon ingestion, inhalation, intravenous injection, or dermal absorption is highly variable depending on the compound but often includes confusion, ataxia, lethargy, and headache. With significant exposure, syncope, coma, and respiratory arrest may occur. Cardiac arrhythmias may occur owing to myocardial sensitization, especially with halogenated and aromatic compounds. With many agents, hepatic and renal injury may occur.
 - D. Injection** of hydrocarbons can cause local tissue inflammation, pain, and necrosis. Severe scarring and loss of function has occurred after injection into a finger with a paint gun or other high-pressure spray device containing a hydrocarbon solvent. Often the puncture wound and local swelling appear minor, but tracking of hydrocarbon solvent down fascial planes into the palm may cause widespread inflammation and injury.
 - E. Skin or eye contact** may cause local irritation, burns, or corneal injury. Chronic skin exposure often causes a defatting dermatitis (resulting from removal of oils from the skin). Some agents are absorbed through the skin and can produce systemic effects.
- IV. Diagnosis**
- A. Aspiration pneumonitis.** Diagnosis is based on a history of exposure and the presence of respiratory symptoms such as coughing, tachypnea, and wheezing. If these symptoms are not present within 6 hours of exposure, it is very unlikely that chemical pneumonitis will occur. Chest x-ray and arterial blood gases or oximetry may assist in the diagnosis of chemical pneumonitis, although chest x-ray findings may be delayed for more than 12–24 hours.
 - B. Systemic intoxication.** Diagnosis is based on a history of ingestion or inhalation, accompanied by the appropriate systemic clinical manifestations.
 - C. Specific levels.** Specific levels are generally not available or useful.
 - D. Other useful laboratory studies.** For suspected aspiration pneumonitis, obtain arterial blood gases or oximetry and a chest x-ray; for suspected systemic toxicity, obtain electrolytes, glucose, BUN, creatinine, and liver transaminases, and perform ECG monitoring.
- V. Treatment**
- A. Emergency and supportive measures**
 - 1. General.** Provide basic supportive care for all symptomatic patients.
 - a.** Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 - b.** Monitor arterial blood gases or oximetry, chest x-ray, and ECG and admit symptomatic patients to an intensive care setting.

- c. Use epinephrine and other sympathomimetic amines with caution in patients with significant hydrocarbon intoxication, because arrhythmias may be induced.
 2. **Pulmonary aspiration.** Patients who remain completely asymptomatic after 4–6 hours of observation may be discharged. In contrast, if the patient is coughing on arrival, aspiration has probably occurred.
 - a. Administer supplemental oxygen, and treat bronchospasm (see p 8) and hypoxia (p 7) if they occur.
 - b. Do **not** use steroids or prophylactic antibiotics.
 3. **Ingestion.** In the vast majority of accidental childhood ingestions, less than 5–10 mL is actually swallowed and systemic toxicity is rare. Treatment is primarily supportive.
 4. **Injection.** For injections into the fingertip or hand, especially if involving a high-pressure paint gun, consult with a plastic or hand surgeon immediately, as prompt wide exposure, irrigation, and debridement are often required.
- B. Specific drugs and antidotes**
1. There is no specific antidote for aspiration pneumonitis; corticosteroids are of no proven value.
 2. Specific drugs or antidotes may be available for systemic toxicity of some hydrocarbons (eg, acetylcysteine for carbon tetrachloride and methylene blue for methemoglobin formers) or their solutes (eg, chelation therapy for leaded gasoline and antidotes for pesticides, etc).
- C. Decontamination**
1. **Inhalation.** Move the victim to fresh air and administer oxygen if available.
 2. **Skin and eyes.** Remove contaminated clothing and wash exposed skin with water and soap. Irrigate exposed eyes with copious tepid water or saline and perform fluorescein examination for corneal injury.
 3. **Ingestion** (see p 47). For agents with no known systemic toxicity, gut decontamination is neither necessary nor desirable because any gut-emptying procedure increases the risk of aspiration. For systemic toxins:
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because systemic complications such as seizures and coma may occur rapidly or abruptly.
 - b. **Hospital.** Administer activated charcoal. Consider gastric lavage for large recent ingestions.
 4. **Injection.** See A. 4. above.
- D. Enhanced elimination.** There is no known role for any of these procedures.

Mirzayan R et al: Culture results and amputation rates in high-pressure paint gun injuries of the hand. *Orthopedics* 2001;24(6):587–589. [PMID: 11430740] (Retrospective review found 50% amputation rate for injections of oil-based paints; 47% of wound cultures were positive and the authors advise use of antibiotics in addition to other measures.)

► HYDROGEN FLUORIDE AND HYDROFLUORIC ACID

Binh T. Ly, MD

Hydrogen fluoride (HF) is an irritant gas that liquefies at 19.5°C; in aqueous solution it produces hydrofluoric acid. HF gas is used in chemical manufacturing. In addition, it may be released from fluorosilicates, fluorocarbons, or Teflon when heated to over 350°C. Hydrofluoric acid (aqueous HF solution) is widely used as a rust remover, in glass etching, and in the manufacture of silicon semiconductor chips. Hydrofluoric acid poisoning usually occurs after dermal exposure, although ingestions occasionally occur. Similar toxicity can result from exposure to ammonium bifluoride.

- I. Mechanism of toxicity.** HF is a skin and respiratory irritant. Hydrofluoric acid is a relatively weak acid (the dissociation constant is about 1000 times less than that of hydrochloric acid), and toxic effects result primarily from the highly reactive fluoride ion.
- A.** HF is able to penetrate tissues deeply, where the highly cytotoxic fluoride ion is released and cellular destruction occurs.
 - B.** In addition, fluoride readily precipitates with calcium; this may cause local bone demineralization and systemic hypocalcemia.
- II. Toxic dose.** Toxicity depends on the air levels of HF or concentration of aqueous HF solutions.
- A. Hydrogen fluoride gas.** The recommended workplace ceiling limit (ACGIH TLV-C) for HF gas is 3 ppm (2.3 mg/m³); 30 ppm is considered immediately dangerous to life or health (IDLH). A 5-minute exposure to air concentrations of 50–250 ppm is likely to be lethal.
 - B. Aqueous solutions.** Solutions of 50–70% are highly toxic and produce immediate pain; concomitant inhalation exposure may occur with exposure to higher concentrations due to release of HF gas. Intermediate concentrations (20–40%) may cause little pain initially but result in deep injury after a delay of 1–8 hours; weak solutions (5–15%) cause almost no pain on contact but may cause delayed serious injury after 12–24 hours. Most household products containing aqueous HF contain 5–8% or less.
- III. Clinical presentation.** Symptoms and signs depend on the type of exposure (gas or liquid) and the concentration.
- A. Inhalation** of HF gas produces ocular, nasal, and oropharyngeal irritation, coughing, and bronchospasm. After a delay of up to several hours, chemical pneumonia and pulmonary edema may occur.
 - B. Skin exposure.** After acute exposure to weak (5–15%) or intermediate (20–40%) solutions, there may be no symptoms because the pH effect is relatively weak. Concentrated (50–70%) solutions have better warning properties because of immediate pain. After a delay of 1–12 hours, progressive redness, swelling, skin blanching, and pain occur owing to deep penetration by the fluoride ion. The exposure is typically through a pinhole-sized defect in a rubber glove, and the fingertip is the most common site of injury. The pain is progressive and unrelenting. Severe deep-tissue destruction may occur, including full-thickness skin loss and destruction of underlying bone.
 - C. Ingestion** of HF may cause corrosive injury to the mouth, esophagus, and stomach.
 - D. Systemic hypocalcemia** and **hyperkalemia** may occur after ingestion or skin burns involving a large body surface area or highly concentrated solutions (can occur with exposure to > 2.5% body surface area and a highly concentrated solution).
- IV. Diagnosis** is based on a history of exposure and typical findings. Immediately after exposure to weak or intermediate solutions, there may be few or no symptoms even though potentially severe injury may develop later.
- A. Specific levels.** Serum fluoride concentrations are not useful after acute exposure but may be used in evaluating chronic occupational exposure. Normal serum fluoride is less than 20 mcg/L, but varies considerably with dietary and environmental intake. In workers, preshift urine excretion of fluoride should not exceed 3 mg/g of creatinine.
 - B. Other useful laboratory studies** include electrolytes, BUN, creatinine, calcium, and continuous ECG monitoring.
- V. Treatment**
- A. Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen. Treat pulmonary edema (p 7) if it occurs.
 2. Patients with HF ingestion should be evaluated for corrosive injury, with consultation by a gastroenterologist or surgeon for possible endoscopy (p 157). All HF ingestions should be considered potentially life threatening.

3. Monitor the ECG and serum calcium and potassium levels; give intravenous calcium (p 424; and see below) if there is evidence of hypocalcemia or severe hyperkalemia.
- B. Specific drugs and antidotes. Calcium** (see p 424) rapidly precipitates fluoride ions and is an effective antidote for fluoride skin exposure and for systemic hypocalcemia resulting from absorbed fluoride.
 1. **Skin burns.** For exposures involving the hands or fingers, immediately consult an experienced hand surgeon, medical toxicologist, or Poison Control Center ([800] 222-1222). Historically, fingernail removal has been utilized but this can result in disfiguring morbidity. Occasionally calcium will need to be given by the intra-arterial route or by intravenous Bier block technique. **Caution:** Do **not** use calcium **chloride** salt for subcutaneous or intra-arterial injections; this form contains a larger proportion of calcium ion compared with the gluconate salt and may cause vasospasm and tissue necrosis.
 - a. **Topical.** Apply a gel containing calcium gluconate or carbonate (see p 424) using an occlusive dressing or a rubber glove to enhance skin penetration. Alternately, soak in a quaternary ammonium solution such as Zephiran (1.3 g/L of water) or an Epsom salt solution. If pain is not significantly improved within 30–60 minutes, consider subcutaneous or intra-arterial injection.
 - b. **Subcutaneous.** Inject calcium gluconate 5–10% subcutaneously in affected areas, using a 27- or 30-gauge needle and no more than 0.5 mL per digit or 1 mL/cm² in other regions.
 - c. **Intra-arterial.** Injection of calcium by the intra-arterial route (see p 424) may be necessary for burns involving several digits or subungual areas.
 - d. **Bier block.** This intravenous regional perfusion technique has been reportedly useful.
 2. **Systemic hypocalcemia or hyperkalemia.** Administer calcium gluconate 10%, 0.2–0.4 mL/kg IV, or calcium chloride 10%, 0.1–0.2 mL/kg IV.
- C. Decontamination** (see p 46). Rescuers entering a contaminated area should wear self-contained breathing apparatus and appropriate protective clothing to avoid personal exposure.
 1. **Inhalation.** Immediately remove victims from exposure and give supplemental oxygen if available. The use of 2.5% calcium gluconate by nebulization is recommended by some authorities.
 2. **Skin.** Immediately flood exposed areas with water. Then soak in a solution of Epsom salts (magnesium sulfate) or calcium; immediate topical use of calcium or magnesium may prevent deep burns. Some facilities that frequently manage HF cases purchase or prepare a 2.5% calcium gluconate gel (in water-based jelly), and this can be highly effective if applied immediately. Soaking in a dilute benzalkonium chloride (Zephiran) solution has been advocated as an alternative to calcium.
 3. **Eyes.** Flush with copious water or saline. The effectiveness of a weak (1–2%) calcium gluconate solution is not established. Consult with an ophthalmologist if there is evidence or suspicion of ocular exposure.
 4. **Ingestion** (see p 47)
 - a. **Prehospital.** Immediately give any available calcium-containing (calcium carbonate or milk) or magnesium-containing (Epsom salts, magnesium hydroxide, etc) substance by mouth. Do **not** induce vomiting because of the risk of corrosive injury. Activated charcoal is not effective.
 - b. **Hospital.** Consider gastric suctioning with a nasogastric tube. Administer magnesium- or calcium-containing substance as in **4.a** above.
- D. Enhanced elimination.** There is no role for enhanced elimination procedures.

investigated nine HF-related deaths; four followed skin contact with concentrated solutions, and five involved both skin contact and inhalation of vapor.)

Lin TM et al: Continuous intra-arterial infusion therapy in hydrofluoric acid burns. *J Occup Environ Med* 2000;42(9):892–897. [PMID: 10998764] (Case series of 10 patients with HF hand exposure treated successfully with intra-arterial calcium infusions.)

► HYDROGEN SULFIDE

Stephen W. Munday, MD, MPH, MS

Hydrogen sulfide is a highly toxic, flammable, colorless gas that is heavier than air. It is produced naturally by decaying organic matter and is also a by-product of many industrial processes. Hazardous levels may be found in petroleum refineries, tanneries, mines, pulp-making factories, sulfur hot springs, carbon disulfide production, commercial fishing holds, hot asphalt fumes, and pools of sewage sludge or liquid manure. It is sometimes referred to as “pit gas.”

- I. **Mechanism of toxicity.** Hydrogen sulfide causes cellular asphyxia by inhibition of the cytochrome oxidase system, similar to the action of cyanide. Because it is rapidly absorbed by inhalation, symptoms occur nearly immediately after exposure, leading to rapid unconsciousness or “knockdown.” Hydrogen sulfide is also a mucous membrane irritant.
- II. **Toxic dose.** The characteristic rotten egg odor of hydrogen sulfide is detectable at concentrations as low as 0.025 ppm. The recommended workplace limit (ACGIH TLV-TWA) is 10 ppm (14 mg/m³) as an 8-hour time-weighted average, with a short-term exposure limit (STEL) of 15 ppm (21 mg/m³). The Federal OSHA permissible exposure limit (PEL) is 20 ppm as a 15-minute ceiling during an 8-hour workday. Marked respiratory tract irritation occurs with levels of 50–100 ppm. Olfactory nerve paralysis occurs with levels of 100–150 ppm. The level considered immediately dangerous to life or health (IDLH) is 100 ppm. Pulmonary edema occurs at levels of 300–500 ppm. Levels of 600–800 ppm are rapidly fatal.
- III. **Clinical presentation**
 - A. **Irritant effects.** Upper-airway irritation, burning eyes, and blepharospasm may occur at relatively low levels. Skin exposure can cause painful dermatitis. Chemical pneumonitis and noncardiogenic pulmonary edema may occur after a delay of several hours.
 - B. **Acute systemic effects** include headache, nausea and vomiting, dizziness, confusion, seizures, and coma. Massive exposure may cause immediate cardiovascular collapse, respiratory arrest, and death. Survivors may be left with serious neurologic impairment.
- IV. **Diagnosis** is based on a history of exposure and rapidly progressive manifestations of airway irritation and cellular asphyxia, with sudden collapse. The victim or coworkers may describe the smell of rotten eggs, but because of olfactory nerve paralysis the absence of this smell does not rule out exposure. Silver coins in the pockets of victims have been blackened (by conversion to silver sulfide).
 - A. **Specific levels** are not available (sulfide is unstable in vitro). Sulfhemoglobin is not thought to be produced after hydrogen sulfide exposure.
 - B. **Other useful laboratory studies** include electrolytes, glucose, arterial blood gases, and chest x-ray.
- V. **Treatment**
 - A. **Emergency and supportive measures.** **Note:** Rescuers should use self-contained breathing apparatus to prevent personal exposure.
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer high-flow humidified supplemental oxygen. Observe for several hours for delayed-onset chemical pneumonia or pulmonary edema (p 7).
 2. Treat coma (see p 19), seizures (p 22), and hypotension (p 16) if they occur.

- B. Specific drugs and antidotes.** Theoretically, administration of nitrites (see p 476) to produce methemoglobinemia may promote conversion of sulfide ions to sulfmethemoglobin, which is far less toxic. However, there is limited evidence for the effectiveness of nitrites, and they can cause hypotension and impaired oxygen delivery. Animal data and limited human case reports have suggested that hyperbaric oxygen (HBO, see p 482) may be helpful if provided early after exposure, but this therapy remains unproven.
- C. Decontamination** (see p 46). Remove the victim from exposure and give supplemental oxygen if available.
- D. Enhanced elimination.** There is no role for enhanced elimination procedures. Although hyperbaric oxygen therapy has been promoted for treatment of hydrogen sulfide poisoning, this is based on anecdotal cases and there is no convincing rationale or scientific evidence for its effectiveness.

Gabbay DS et al: Twenty-foot fall averts fatality from massive hydrogen sulfide exposure. *J Emerg Med* 2001;20(2):141–144. [PMID: 11207408] (The “knockdown” effect of acute exposure to > 1000 ppm hydrogen sulfide resulted in a mechanical fall from a tall ladder, ironically saving the victim’s life by rapidly removing him from the exposure.)

Kage S et al: Fatal and nonfatal poisoning by hydrogen sulfide at an industrial waste site. *J Forensic Sci* 2002;47(3):652–655. [PMID: 12051356] (Three workers died after one entered an industrial waste pit and three others attempted to rescue him when he lost consciousness. Concentrations of thiosulfate in the blood and urine were more useful than sulfide levels.)

► HYMENOPTERA

Richard F. Clark, MD

Venomous insects are grouped into four families of the order Hymenoptera: Apidae (honeybees), Bombidae (bumblebees), Vespidae (wasps, hornets, and yellow jackets), and Formicidae (ants). With the exception of Vespidae, most bees sting only when disturbed or when the hive is threatened. Yellow jackets may attack without provocation and are the most common cause of insect-induced anaphylactic reactions.

- I. Mechanism of toxicity.** The venoms of Hymenoptera are complex mixtures of enzymes and are delivered by various methods. The venom apparatus is located in the posterior abdomen of the females.
- A.** The terminal end of the stinger of the **Apidae** (honeybee) is barbed, so the stinger remains in the victim and some or all of the venom apparatus will be torn from the body of the bee, resulting in its death as it flies away. The musculature surrounding the venom sac continues to contract for several minutes, causing venom to be persistently ejected. The **Bombidae** and **Vespidae** have stingers that remain functionally intact after a sting, resulting in their ability to inflict multiple stings.
- B.** The envenomating **Formicidae** have secretory venom glands in the posterior abdomen and envenomate either by injecting venom through a stinger or by spraying venom from the posterior abdomen into a bite wound produced by their mandibles.
- II. Toxic dose.** The dose of venom delivered per sting may vary from none to the entire contents of the venom gland. The toxic response is highly variable depending on individual sensitivity. Some Hymenoptera, such as wasps, have the ability to sting several times, increasing the venom load. Disturbing a fire ant nest may result in as many as 3000–5000 stings within seconds.
- III. Clinical presentation.** The patient may present with signs of envenomation or an allergic reaction.
- A. Envenomation.** Once venom is injected, there is usually immediate onset of severe pain followed by a local inflammatory reaction that may include erythema, wheal formation, ecchymosis, edema, vesiculation and blisters, itch-

ing, and a sensation of warmth. Multiple stings, and very rarely severe single stings, may also produce vomiting, diarrhea, hypotension, syncope, cyanosis, dyspnea, rhabdomyolysis, coagulopathy, and death.

- B. Allergic reactions.** Numerous deaths occur annually in the United States from immediate hypersensitivity (anaphylactic) reactions characterized by urticaria, angioedema, bronchospasm, and shock. Most anaphylactic reactions occur within 15 minutes of envenomation. Rarely, delayed-onset reactions may occur, including Arthus reactions (arthralgias and fever), nephritis, transverse myelitis, and Guillain-Barré syndrome. Cross-sensitivity to fire ant venom can exist in some patients with apid or vespoid allergies.

IV. Diagnosis is usually obvious from the history of exposure and typical findings.

- A. Specific levels.** Not relevant.
B. Other useful laboratory studies. None.

V. Treatment

A. Emergency and supportive measures

1. Monitor the victim closely for at least 30–60 minutes.
2. Treat anaphylaxis (see p 27), if it occurs, with epinephrine (p 442) and diphenhydramine (p 436) or hydroxyzine. Persistent urticaria may respond to the addition of cimetidine, 300 mg PO or IV, or another H₂ receptor antagonist. Persons known to be sensitive to Hymenoptera venom should wear medical alert jewelry and carry an epinephrine emergency kit at all times.
3. In most cases the painful localized tissue response will resolve in a few hours without therapy. Some symptomatic relief may be obtained by topical application of ice, papain (meat tenderizer), or creams containing corticosteroids or antihistamines.
4. Provide tetanus prophylaxis if appropriate.

B. Specific drugs and antidotes. There is no available antidote.

C. Decontamination. Examine the sting site carefully for any retained stingers; these can be removed by gentle scraping with a sharp edge (eg, knife blade) or with tweezers (venom gland contents have almost always been quickly and completely expelled). Wash the area with soap and water.

D. Enhanced elimination. These procedures are not applicable.

Diaz-Sanchez CL et al: Survival after massive (>2000) Africanized honeybee stings. *Arch Intern Med* 1998;158(8):925–927. [PMID: 9570180] (The victim survived anaphylactic shock and multisystem organ failure.)

Volcheck GW: Hymenoptera (apid and vespoid) allergy: update in diagnosis and management. *Curr Allergy Asthma Rep* 2002;2(1):46–50. [PMID: 11895625] (Review of skin testing and immunotherapy.)

► IODINE

Walter H. Mullen, PharmD

The chief use of iodine is for its antiseptic property. It is bactericidal, sporicidal, protozoacidal, cysticidal, and virucidal. Because it is poorly soluble in water, liquid formulations are usually prepared as a tincture in ethanol (50% or higher). Iodoform, iodochlorhydroxyquin, iodophors (povidone-iodine), and sodium and potassium iodides also exert their bactericidal effect by liberating iodine. Lugol's solution (5% iodine and 10% potassium iodide) is used in the treatment of hyperthyroidism and for the prevention of radioactive iodine absorption after nuclear accidents. The antiarrhythmic drug amiodarone releases iodine and may cause thyrotoxicosis after prolonged use. Iodine is also used in the manufacture of dyes and photographic reagents.

- I. Mechanism of toxicity.** Iodine is corrosive because of its oxidizing properties. When ingested, iodine is poorly absorbed but may cause severe gastroenteritis. Iodine is readily inactivated by starch to convert it to iodide, which is nontoxic. In the body, iodine is rapidly converted to iodide and stored in the thyroid gland.

- II. The toxic dose** depends on the product and the route of exposure. Iodophors and iodoform liberate only small amounts of iodine and are generally nontoxic and noncaustic.
- A. Iodine vapor.** The ACGIH-recommended workplace ceiling limit (TLV-C) for iodine vapor is 0.1 ppm (1 mg/m³). The air level considered immediately dangerous to life or health (IDLH) is 2 ppm.
- B. Skin and mucous membranes.** Strong iodine tincture (7% iodine and 5% potassium iodide in 83% ethanol) may cause burns, but USP iodine tincture (2% iodine and 2% sodium iodide in 50% ethanol) is not likely to produce corrosive damage. Systemic absorption of iodine may occur after an acute application of strong iodine tincture or after chronic applications of less concentrated products.
- C. Ingestion.** Reported fatal doses vary from 200 mg to more than 20 g of iodine; an estimated mean lethal dose is approximately 2–4 g of free iodine. USP iodine tincture contains 100 mg iodine per 5 mL, and strong iodine tincture contains 350 mg of iodine per 5 mL. Iodine ointment contains 4% iodine. Consider ethanol toxicity with large exposures (see p 190).
- III. Clinical presentation.** The manifestations of iodine poisoning are largely related to its corrosive effect on mucous membranes.
- A. Inhalation** of iodine vapor can cause severe pulmonary irritation leading to pulmonary edema.
- B. Skin** and eye exposures may result in severe corrosive burns.
- C. Ingestion** can cause corrosive gastroenteritis with vomiting, hematemesis, and diarrhea, which can result in significant volume loss and circulatory collapse. Pharyngeal swelling and glottic edema have been reported. Mucous membranes are usually stained brown, and the vomitus may be blue if starchy foods are already present in the stomach.
- D. Chronic** ingestions or absorption may result in hypothyroidism and goiter. Iodides cross the placenta, and neonatal hypothyroidism and death from respiratory distress secondary to goiter have been reported.
- IV. Diagnosis** is based on a history of exposure and evidence of corrosive injury. Mucous membranes are usually stained brown, and vomitus may be blue.
- A. Specific levels.** Blood levels are not clinically useful but may confirm exposure.
- B. Other useful laboratory studies** include, for serious corrosive injury, CBC, electrolytes, BUN, and creatinine. For serious inhalation, arterial blood gases or oximetry and chest x-ray are useful.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and perform endotracheal intubation if airway edema is progressive (see pp 1–7). Treat bronchospasm (see p 8) and pulmonary edema (p 7) if they occur.
 2. Treat fluid loss from gastroenteritis aggressively with intravenous crystalloid solutions.
 3. If corrosive injury to the esophagus or stomach is suspected, consult a gastroenterologist to perform endoscopy.
- B. Specific drugs and antidotes.** Sodium thiosulfate may convert iodine to iodide and tetrathionate, but is not recommended for intravenous use because iodine is rapidly converted to iodide in the body.
- C. Decontamination** (see p 46)
1. **Inhalation.** Remove the victim from exposure.
 2. **Skin and eyes.** Remove contaminated clothing and flush exposed skin with water. Irrigate exposed eyes copiously with tepid water or saline for at least 15 minutes.
 3. **Ingestion** (see p 47)
 - a. **Prehospital.** Do **not** induce vomiting because of the corrosive effects of iodine. Administer a starchy food (potato, flour, or cornstarch) or milk to lessen gastrointestinal irritation.

b. Hospital. For large exposures, consider gastric lavage, using milk, cornstarch, or sodium thiosulfate. Activated charcoal is of unknown efficacy.

D. Enhanced elimination. Once absorbed into the circulation, iodine is rapidly converted to the far less toxic iodide. Therefore, there is no need for enhanced drug removal.

Kurt TL et al: Fatal iatrogenic iodine toxicity in a nine-week old infant. *J Toxicol Clin Toxicol* 1996;34(2):231–234. [PMID: 8618260] (A 9-week-old infant with colic was given an enema using 50 mL of povidone-iodine diluted in 250 mL of a bowel irrigant, resulting in fatal corrosive necrosis of the lower GI tract and total blood iodine level of 14,600 mcg/dL.)

► IPECAC SYRUP

Chulathida G. Chomchai, MD

Ipecac syrup is an alkaloid derivative of the ipecacuanha plant (*Cephaeline ipecacuanha*). The principal alkaloids, emetine and cephaeline, both have emetogenic properties. The emetine extract has been used for the treatment of amebiasis. Syrup of ipecac is widely available over the counter as an effective, rapidly acting emetic agent. Presently, the major source of poisoning is chronic intoxication resulting from intentional misuse by patients with eating disorders. Cases of “Munchausen’s syndrome by proxy,” in which a parent repeatedly administers ipecac to a child, have also been reported.

I. Mechanism of toxicity

A. Mechanism of action. Ipecac causes vomiting in two phases: by direct irritation of the gastric mucosa and by systemic absorption and stimulation of the central chemoreceptor trigger zone.

B. Acute ingestion can cause profuse vomiting and diarrhea, especially with ingestion of the more concentrated fluid extract (no longer available in the United States).

C. Chronic repeated dosing. The emetine component causes inhibition of protein synthesis that is particularly demonstrated in human myocytes and skeletal muscle cells after overdose or prolonged use. Another proposed mechanism for cellular toxicity includes blockade of sodium and calcium channels.

II. Toxic dose. Toxicity depends on the formulation and whether the exposure is acute or chronic.

A. Acute ingestion of 60–120 mL of **syrup of ipecac** is not likely to cause serious poisoning. However, the **fluid extract**, which is approximately 14 times more potent than syrup of ipecac, has caused death after ingestion of as little as 10 mL.

B. Chronic dosing results in cumulative toxicity because of the slow elimination of emetine. Repeated ingestion over time, as in cases of Munchausen by proxy or eating disorders, has been reported to cause myotoxicity with total accumulated doses of 600–1250 mg. Daily ingestion of 90–120 mL of syrup of ipecac for 3 months caused death from cardiomyopathy.

III. Clinical presentation

A. Acute ingestion of ipecac causes nausea and vomiting. In patients with depressed airway-protective reflexes, pulmonary aspiration of gastric contents may occur. Prolonged or forceful vomiting may cause gastritis, gastric rupture, pneumomediastinum, retropneumoperitoneum, or Mallory-Weiss tears of the cardioesophageal junction. One fatal case of intracerebral hemorrhage was reported in an elderly patient after a single therapeutic dose of ipecac syrup.

B. Chronic intoxication. In patients with chronic misuse, dehydration and electrolyte abnormalities (eg, hypokalemia) occur as a result of frequent vomiting

and diarrhea, and myopathy or cardiomyopathy may develop. Symptoms of myopathy include muscle weakness and tenderness, hyporeflexia, and elevated serum CPK. Cardiomyopathy, with congestive heart failure and arrhythmias, may be fatal.

1. Munchausen by proxy. Children intentionally poisoned with ipecac typically have a history of recurrent hospitalizations for vomiting that seems refractory to outpatient medical treatment. The symptoms usually improve in the hospital but worsen when the child returns home. Progressive weight loss and loss of developmental milestones are commonly seen. Physical examination reveals muscle weakness and other signs of chronic myopathy. Some children have been reported to develop a secondary eating disorder, such as rumination, as a result of their recurrent vomiting.

2. Adults with an eating disorder and frequent use of ipecac often present with a history of recent weight loss. Malnutrition and chronic vomiting may cause electrolyte disturbances, dental changes, and skin changes associated with various vitamin deficiencies.

IV. Diagnosis is based on a careful history of ingestion. Chronic ipecac poisoning should be suspected in any patient with an eating disorder and evidence of dehydration, electrolyte imbalance, or myopathy, or in a young child with repeated unexplained episodes of vomiting, diarrhea, and failure to thrive. The electrocardiogram may show prolonged QRS and QT intervals, flat or inverted T waves, and supraventricular and ventricular arrhythmias.

A. Specific levels. Emetine may be detected in the urine for up to several weeks after ingestion, and its presence may provide qualitative confirmation of ipecac exposure but does not correlate with the degree of effect. It is not part of a routine comprehensive toxicology screen and must be specifically requested. Levels as low as 95 ng/mL in urine and 21 ng/mL in blood have been found in cases of confirmed Munchausen by proxy. A urinary level of 1700 ng/mL was found in a 4-year-old child who died after chronic vomiting, diarrhea, and failure to thrive. Pathologic findings of the heart muscle included marked autolytic changes with swollen mitochondria and fragmented irregular alignment of Z bands.

B. Other useful laboratory studies include electrolytes, BUN, creatinine, CPK, lactate dehydrogenase (LDH), and ECG.

V. Treatment

A. Emergency and supportive measures

1. Correct fluid and electrolyte abnormalities with intravenous fluids and potassium as needed.
2. Diuretics and pressor support may be required in patients with congestive cardiomyopathy.
3. Monitor the ECG for 6–8 hours, and admit patients with evidence of myopathy or cardiomyopathy. Treat arrhythmias with standard drugs (see pp 10–15).

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (acute ingestions only; see p 47).

1. **Prehospital.** Administer activated charcoal, if available. Obviously, do not administer ipecac.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for very large ingestions.

D. Enhanced elimination. There is no known role for enhanced elimination. The alkaloids are highly bound to tissue.

Bader AA, Kerzner B: Ipecac toxicity in "Munchausen syndrome by proxy." *Ther Drug Monit* 1999;21(2):259–260. Erratum in: *Ther Drug Monit* 1999;21(4):487. [PMID: 10217350] (Case report.)

Ho PC et al: Rapidly reversible cardiomyopathy associated with chronic ipecac ingestion. *Clin Cardiol* 1998;21(10):780–783. [PMID: 9789704] (Left ventricular dysfunction resolved after just 10 days of withholding the ipecac from a young woman with anorexia nervosa and bulimia.)

► IRON

Anthony S. Manoguerra, PharmD

Iron is widely used for treatment of anemia, for prenatal supplementation, and as a common daily vitamin supplement. Because of its wide availability and its presumed harmlessness as a common over-the-counter nutritional supplement, it remains one of the most common childhood ingestions and is the leading cause of fatal poisonings in children. There are many different iron preparations, containing various amounts of iron salts. Most children's preparations contain 12–18 mg of elemental iron per dose, and most adult preparations contain 60–90 mg of elemental iron per dose.

- I. **Mechanism of toxicity.** Toxicity results from direct corrosive effects and cellular toxicity.
 - A. Iron has a direct **corrosive effect** on mucosal tissue and may cause hemorrhagic necrosis and perforation. Fluid loss from the gastrointestinal tract results in severe hypovolemia.
 - B. **Absorbed iron** in excess of protein binding capacity causes cellular dysfunction, resulting in lactic acidosis and necrosis. The exact mechanism for cellular toxicity is not known, but iron ligands can cause oxidative and free-radical injury.
- II. **Toxic dose.** The acute lethal dose in animal studies is 150–200 mg/kg of elemental iron. The lowest reported lethal dose in a child was 600 mg. Symptoms are unlikely if less than 20 mg/kg of elemental iron has been ingested. Doses of 20–30 mg/kg may produce self-limited vomiting, abdominal pain, and diarrhea. Ingestion of more than 40 mg/kg is considered potentially serious, and more than 60 mg/kg potentially lethal.
- III. **Clinical presentation.** Iron poisoning is usually described in four stages, although the clinical manifestations may overlap.
 - A. Shortly after ingestion, the corrosive effects of iron cause vomiting and diarrhea, often bloody. Massive fluid or blood loss into the gastrointestinal tract may result in shock, renal failure, and death.
 - B. Victims who survive this phase may experience a latent period of apparent improvement over 12 hours.
 - C. This may be followed by an abrupt relapse with coma, shock, seizures, metabolic acidosis, coagulopathy, hepatic failure, and death. *Yersinia enterocolitica* sepsis may occur.
 - D. If the victim survives, scarring from the initial corrosive injury may result in pyloric stricture or other intestinal obstructions.
- IV. **Diagnosis** is based on a history of exposure and the presence of vomiting, diarrhea, hypotension, and other clinical signs. Elevation of the white blood count ($> 15,000$) or blood glucose (> 150 mg/dL) or visible radiopaque pills on abdominal x-ray also suggest significant ingestion. Serious toxicity is very unlikely if the white count, glucose, and x-ray are normal and there is no spontaneous vomiting or diarrhea.
 - A. **Specific levels.** If the total serum iron level is higher than 450–500 mcg/dL, toxicity is more likely to be present. Serum levels higher than 800–1000 mcg/dL are associated with severe poisoning. Determine the serum iron level at 4–6 hours after ingestion, and repeat determinations after 8–12 hours to rule out delayed absorption (eg, from a sustained-release tablet or a tablet bezoar). The total iron-binding capacity (TIBC) is unreliable in iron overdose and should not be used to estimate free iron levels.
 - B. **Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, liver function tests, coagulation studies, and abdominal x-ray.
- V. **Treatment.** Patients who have self-limited mild gastrointestinal symptoms or who remain asymptomatic for 6 hours are unlikely to develop serious intoxication. On the other hand, those few with serious ingestion must be promptly and aggressively managed.

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat shock caused by hemorrhagic gastroenteritis aggressively with intravenous crystalloid fluids (see p 16), and replace blood if needed. Patients are often markedly hypovolemic owing to gastrointestinal losses and third-spacing of fluids into the intestinal wall and interstitial space.
3. Treat coma (see p 19), seizures (p 22), and metabolic acidosis (p 33) if they occur.

B. Specific treatment. For seriously intoxicated victims (eg, shock, severe acidosis, and/or serum iron > 500–600 mcg/dL), administer **deferoxamine** (see p 432). Monitor the urine for the characteristic orange or pink-red (“vin rosé”) color of the chelated deferoxamine-iron complex. Therapy may be stopped when the urine color returns to normal or when the serum iron level decreases to the normal range. Prolonged deferoxamine therapy (longer than 36–72 hours) has been associated with adult respiratory distress syndrome (ARDS) and *Yersinia* sepsis.

1. The intravenous route is preferred: give 10–15 mg/kg/h by constant infusion; faster rates (up to 45 mg/kg/h) have been reportedly well tolerated in single cases, but rapid boluses usually cause hypotension. The recommended maximum daily dose is 6 g, but larger amounts have been safely given in massive iron overdoses.
2. Deferoxamine has also been given intramuscularly (eg, as a test dose in suspected poisonings while awaiting laboratory confirmation); the usual dose is 50 mg/kg, with a maximum of 1 g. However, hypotension can also occur with the intramuscular route, and this route is not recommended.

C. Decontamination (see p 47)

1. **Prehospital.** Activated charcoal is not effective. Ipecac is not recommended, because it can aggravate iron-induced gastrointestinal irritation and interfere with whole-bowel irrigation (see below).

2. Hospital

- a. Consider gastric lavage if the product was a liquid formulation or tablets were chewed (intact tablets are not likely to pass through a lavage tube). Do **not** use phosphate-containing solutions for lavage; these may result in life-threatening hypernatremia, hyperphosphatemia, and hypocalcemia. Bicarbonate and deferoxamine lavage are of doubtful efficacy. Deferoxamine lavage is not effective and may enhance iron absorption.
- b. **Whole-bowel irrigation** (see p 52) is very effective for ingested tablets and may be considered first-line treatment, especially if large numbers of tablets are visible on plain abdominal x-ray.
- c. **Activated charcoal does not adsorb iron** and is not recommended unless other drugs have been ingested.
- d. Massive ingestions may result in tablet concretions or bezoars. Repeated or prolonged whole-bowel irrigation (44.3 L over 5 days in one reported case) may remove the tablets. Endoscopy or surgical gastrotomy is rarely required.

D. Enhanced elimination

1. Hemodialysis and hemoperfusion are not effective at removing iron but may be necessary to remove deferoxamine-iron complex in patients with renal failure.
2. **Exchange transfusion** is occasionally used for massive pediatric ingestion but is of questionable efficacy.

Siff JE et al: Usefulness of the total iron binding capacity in the evaluation and treatment of acute iron overdose. *Ann Emerg Med* 1999 Jan;33(1):73–76. [PMID: 9867890] (Laboratory methods for determining TIBC are highly variable, are inaccurate in the presence of excess iron or deferoxamine, and should not be used in determining toxicity after an acute overdose.)

Tenenbein M: Hepatotoxicity in acute iron poisoning. *J Toxicol Clin Toxicol* 2001;39(7):721–726. [PMID: 11778670] (Acute hepatic failure after iron poisoning is uncommon but carries a high

mortality rate. The lowest reported serum iron concentration associated with hepatotoxicity was 1700 mcg/dL. The periportal areas of the liver are most affected.)

► ISOCYANATES

Paul D. Blanc, MD, MSPH

Toluene diisocyanate (TDI), methylene diisocyanate (MDI), and related chemicals are industrial components in the polymerization of urethane coatings and insulation materials. Most two-part urethane products contain some amount of one of these chemicals, and lesser amounts may contaminate one-part systems. **Methyl isocyanate** (the toxin released in the Bhopal, India, tragedy) is a carbamate insecticide precursor; it is not used in urethanes, has actions different from those of the TDI group of chemicals, and is not discussed here (see Table IV-4, p 593).

- I. **Mechanism of toxicity.** Toluene diisocyanate and related isocyanates act as irritants and sensitizers at very low concentrations. The mechanism is poorly understood, but it is thought that they act as haptens. Once a person is sensitized to one isocyanate, cross-reactivity to others may occur.
- II. **Toxic dose.** The ACGIH-recommended workplace short-term exposure limit (STEL) for TDI is 0.02 ppm (0.14 mg/m³), with a threshold limit value (TLV) of 0.005 ppm (0.036 mg/m³) as an 8-hour time-weighted average. This exposure limit seeks to prevent acute irritant effects. However, in individuals with prior TDI sensitivity, even this level may be hazardous. The level considered immediately dangerous to life or health (IDLH) is 2.5 ppm. Other isocyanates are less volatile, but overexposure can occur from spray aerosols.
- III. **Clinical presentation**
 - A. **Acute exposure** to irritant levels causes skin and upper respiratory tract toxicity. Burning eyes and skin, cough, and wheezing are common. Noncardiogenic pulmonary edema may occur with severe exposure. Symptoms may occur immediately with exposure or may occasionally be delayed several hours.
 - B. **Low-level chronic exposure** may produce dyspnea, wheezing, and other signs and symptoms consistent with asthma. Interstitial lung injury, with radiographic infiltrates and hypoxemia, may occur less commonly.
- IV. **Diagnosis** requires a careful occupational history. Pulmonary function testing may document an obstructive deficit or may be normal. Variable airflow or changing measures of airway reactivity (methacholine or histamine challenge) temporally linked to exposure strongly support the diagnosis of isocyanate-induced asthma.
 - A. **Specific levels.** There are no clinical blood or urine tests for isocyanates.
 1. Test inhalation challenge to isocyanate is not advised except in experienced laboratories owing to the danger of severe asthma attack.
 2. Isocyanate antibody testing, although useful epidemiologically, is difficult to interpret in an individual patient.
 - B. **Other useful laboratory studies** include arterial blood gases or oximetry, chest x-ray, and pulmonary function tests.
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. After acute high-intensity inhalational exposure, maintain an open airway (see pp 1-4), give bronchodilators as needed for wheezing (p 8), and observe for 8-12 hours for pulmonary edema (p 7).
 2. When airway hyperreactivity has been documented, further exposure to isocyanate is contraindicated. Involve public health or OSHA agencies to determine whether other workers are at risk.
 - B. **Specific drugs and antidotes.** There is no specific antidote.
 - C. **Decontamination** after high-level exposure (see p 46)

1. **Inhalation.** Remove the victim from exposure, and give supplemental oxygen if available.
2. **Skin and eyes.** Remove contaminated clothing (liquid or heavy vapor exposure), and wash exposed skin with copious soap and water. Irrigate exposed eyes with copious saline or tepid water.

D. Enhanced elimination. There is no role for these procedures.

Piirila PL et al: Long-term follow-up of hexamethylene diisocyanate-, diphenylmethane diisocyanate-, and toluene diisocyanate-induced asthma. *Am J Respir Crit Care Med* 2000;162(2 Pt 1):516–522. [PMID: 10934080] (Large case series of 245 persons with isocyanate-induced asthma found persistent symptoms in 82% 10 years after diagnosis. Outcome was worse in patients with TDI- and MDI-induced asthma.)

Wisniewski AV, Redlich CA: Recent developments in diisocyanate asthma. *Curr Opin Allergy Clin Immunol* 2001;1(2):169–175. [PMID: 11964686] (Thorough review of the mechanisms of isocyanate-induced lung disease.)

► ISONIAZID (INH)

Andrew Erdman, MD

Isoniazid (INH), a hydrazide derivative of isonicotinic acid, is the bactericidal drug of choice for tuberculosis. INH is well known for its propensity to cause hepatitis with chronic use. Acute isoniazid overdose is a common cause of drug-induced seizures and metabolic acidosis.

I. Mechanism of toxicity

A. Acute overdose. Isoniazid produces acute toxic effects by reducing brain pyridoxal 5-phosphate, which is the active form of vitamin B₆ and an essential cofactor for the enzyme glutamic acid decarboxylase. This results in lower CNS levels of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter, which leads to uninhibited electrical activity manifested as seizures. INH may also inhibit the hepatic conversion of lactate to pyruvate, exacerbating the lactic acidosis from seizures.

B. Chronic toxicity. Peripheral neuritis with chronic use is thought to be related to competition with pyridoxine. The mechanism of chronic hepatic injury and INH-induced systemic lupus erythematosus (SLE) is not discussed here.

C. Pharmacokinetics. Peak absorption occurs in 1–2 hours. The volume of distribution is 0.6–0.7 L/kg. Elimination is by hepatic metabolism; the half-life is 0.5–1.6 hours in fast acetylators, and 2–5 hours in slow acetylators. See also Table II–59.

II. Toxic dose

A. Acute ingestion of as little as 15–40 mg/kg can produce toxicity. Severe toxicity is common after ingestion of 80–150 mg/kg.

B. With chronic use, 10–20% of patients will develop hepatic toxicity when the dose is 10 mg/kg/day, but less than 2% will develop this toxicity if the dose is 3–5 mg/kg/day. Older persons are more susceptible to chronic toxicity.

III. Clinical presentation

A. After acute overdose, nausea, vomiting, slurred speech, ataxia, depressed sensorium, coma, respiratory depression, and seizures may occur rapidly (usually within 30–120 minutes). Profound anion gap metabolic acidosis (pH 6.8–6.9) often occurs after only one or two seizures, probably owing to muscle release of lactic acid. This usually clears slowly even after the seizure activity is controlled. Liver injury may occur after an acute overdose, and may be delayed up to several days. Hemolysis may occur in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Rhabdomyolysis can be a complication of recurrent seizures.

B. Chronic therapeutic INH use may cause peripheral neuritis, hepatitis, hypersensitivity reactions including drug-induced lupus erythematosus, and pyridoxine deficiency.

IV. Diagnosis is usually made by history and clinical presentation. INH toxicity should be considered in any patient with acute-onset seizures, especially if unresponsive to routine anticonvulsant medications and if accompanied by profound metabolic acidosis.

A. Specific levels. Isoniazid is not usually detected in routine toxicology screening. Specific levels may be obtained but are rarely available or helpful for management of acute overdoses. A 5 mg/kg dose produces a peak INH concentration of 3 mg/L at 1 hour (1–7 mg/L is considered antitubercular). Serum levels higher than 30 mg/L are associated with acute toxicity.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver function tests, creatine phosphokinase, and arterial blood gases.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), and metabolic acidosis (p 33) if they occur. Administer diazepam, 0.1–0.2 mg/kg IV, for treatment of seizures.

B. Specific drugs and antidotes. **Pyridoxine** (vitamin B₆) is a specific antidote and usually terminates diazepam-resistant seizures and results in improved mental status. Administer at least 5 g IV (see p 499) if the amount of INH ingested is not known; if the amount is known, give an equivalent amount in grams of pyridoxine to grams of ingested INH. Concomitant treatment with diazepam may improve outcome. If no pyridoxine is available, high-dose diazepam (0.3–0.4 mg/kg) may be effective for status epilepticus. Pyridoxine treatment may also hasten the resolution of metabolic acidosis.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of rapid onset of coma and seizures.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for massive ingestions.

D. Enhanced elimination. Forced diuresis and hemodialysis have been reported to be successful, but are unnecessary for most cases, because the half-life of INH is relatively short (1–5 hours, depending on acetylator status), and toxicity can usually be easily managed with pyridoxine and diazepam. Symptoms generally resolve over a course of 8–24 hours.

Panganiban LR et al: Rhabdomyolysis in isoniazid poisoning. *J Toxicol Clin Toxicol* 2001;39(2):143–151. [PMID: 11407500] (Retrospective review of 270 INH overdoses seen over 5-year period at Philippine General Hospital. Good review of symptoms, lab findings, and incidence of rhabdomyolysis with INH poisoning.)

► ISOPROPYL ALCOHOL

Amy Kunihiro, MD

Isopropyl alcohol is widely used as a solvent, an antiseptic, and a disinfectant and is commonly available in the home as a 70% solution (rubbing alcohol). It is often ingested by alcoholics as a cheap substitute for liquor. Unlike the other common alcohol substitutes methanol and ethylene glycol, isopropyl alcohol is not metabolized to highly toxic organic acids and therefore does not produce a profound anion gap acidosis. Hospitals sometimes color isopropyl alcohol with blue dye to distinguish it from other clear liquids; this has led abusers to refer to it as “blue heaven.”

I. Mechanism of toxicity

A. Isopropyl alcohol is a potent depressant of the CNS, and intoxication by ingestion or inhalation may result in coma and respiratory arrest. It is metabo-

lized to acetone (dimethyl ketone), which may contribute to and prolong CNS depression.

- B. Very large doses of isopropyl alcohol may cause hypotension secondary to vasodilation and possibly myocardial depression.
 - C. Isopropyl alcohol is irritating to the gastrointestinal tract and commonly causes gastritis.
 - D. **Pharmacokinetics.** Isopropyl alcohol is well absorbed and quickly distributes into body water (volume of distribution 0.6 L/kg). It is metabolized (half-life 2.5–3 hours) by alcohol dehydrogenase to acetone.
- II. **Toxic dose.** Isopropyl alcohol is an approximately two- to threefold more potent CNS depressant than ethanol.
- A. **Ingestion.** The toxic oral dose is about 0.5–1 mL/kg of rubbing alcohol (70% isopropyl alcohol) but varies depending on individual tolerance and whether any other depressants were ingested. Fatalities have occurred after adult ingestion of 240 mL, but patients with up to 1-L ingestions have recovered with supportive care.
 - B. **Inhalation.** The odor of isopropyl alcohol can be detected at an air level of 40–200 ppm. The recommended workplace limit (ACGIH TLV-TWA) is 400 ppm (983 mg/m³) as an 8-hour time-weighted average. The air level considered immediately dangerous to life or health (IDLH) is 2000 ppm. Toxicity has been reported in children after isopropyl alcohol sponge baths, probably owing mainly to inhalation as well as skin absorption.
- III. **Clinical presentation.** Intoxication mimics drunkenness from ethanol, with slurred speech, ataxia, and stupor followed in large ingestions by coma, hypotension, and respiratory arrest.
- A. Because of the gastric irritant properties of isopropyl alcohol, abdominal pain and vomiting are common, and hematemesis occasionally occurs.
 - B. Metabolic acidosis may occur but is usually mild. The osmolar gap is usually elevated (see p 32).
 - C. Isopropyl alcohol is metabolized to **acetone**, which contributes to CNS depression and gives a distinct odor to the breath (in contrast, methanol and ethylene glycol and their toxic metabolites are odorless). Acetone is also found in nail polish remover and is widely used as a solvent in industry and chemical laboratories.
- IV. **Diagnosis** is usually based on a history of ingestion and the presence of an elevated osmolar gap, the absence of severe acidosis, and the characteristic smell of isopropyl alcohol or its metabolite, acetone. Ketonemia and ketonuria may be present within 1–3 hours of ingestion.
- A. **Specific levels.** Serum isopropyl alcohol and acetone levels are usually available through commercial toxicology laboratories. The serum level may also be estimated by calculating the osmolar gap (see Table I–22, p 32). Isopropyl alcohol levels higher than 150 mg/dL usually cause coma, but patients with levels up to 560 mg/dL have survived with supportive care and dialysis. Serum acetone concentrations may be elevated.
 - B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, serum osmolality and osmolar gap, and arterial blood gases or oximetry.
- V. **Treatment**
- A. **Emergency and supportive measures**
 - 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 - 2. Treat coma (see p 19), hypotension (p 16), and hypoglycemia (p 34) if they occur.
 - 3. Admit and observe symptomatic patients for at least 6–12 hours.
 - B. **Specific drugs and antidotes.** There is no specific antidote. Ethanol therapy is **not** indicated because isopropyl alcohol does not produce a toxic organic acid metabolite.
 - C. **Decontamination** (see p 46). Because isopropyl alcohol is rapidly absorbed after ingestion, gastric emptying procedures are not likely to be useful if the

ingestion is small (a swallow or two) or if more than 30 minutes has passed. For large ingestions:

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of rapidly developing coma.
2. **Hospital.** Administer activated charcoal. Although isopropyl alcohol adsorbs poorly to charcoal, approximately 1 g of charcoal will bind 1 mL of 70% alcohol. Consider gastric lavage for very large recent ingestions.

D. Enhanced elimination

1. **Hemodialysis** effectively removes isopropyl alcohol and acetone but is rarely indicated because the majority of patients can be managed with supportive care alone. Dialysis should be considered when levels are extremely high (eg, > 500–600 mg/dL) or if hypotension does not respond to fluids and vasopressors.
2. Hemoperfusion, repeat-dose charcoal, and forced diuresis are not effective.

Stremski E, Hennes H: Accidental isopropanol ingestion in children. *Pediatr Emerg Care* 2000;16(4):238–240. [PMID: 10966340] (Retrospective review of 91 children who presented to an emergency department after isopropyl alcohol ingestion. Toxicity was noted in 26 children, and included spontaneous emesis in 24, ataxia in 5, altered mental status in 3, and apnea in one child. Toxicity developed within 0.5–2 hours after ingestion, and was more likely if more than 1 ounce was ingested.)

► JELLYFISH AND OTHER CNIDARIA

Susan Kim, PharmD

The large phylum Cnidaria (coelenterates), numbering about 5000 species, includes **fire coral, Portuguese man-o-war, box jellyfish, sea nettle, and anemones**. Despite considerable morphologic variation, all of these organisms have venom contained in microscopic structures like water balloons, called nematocysts.

- I. **Mechanism of toxicity.** Each nematocyst contains a small ejectable thread soaking in viscous venom. The thread has a barb on the tip and is fired from the nematocyst with enough velocity to pierce human skin. The nematocysts are contained in outer sacs (cnidoblasts) arranged along the tentacles stretched out in the water beneath the body of the jellyfish or along the surface of fire coral and the finger-like projections of sea anemones. When the cnidoblasts are opened by hydrostatic pressure, physical contact, changes in osmolarity, or chemical stimulants as yet unidentified, they release their nematocysts, which eject the thread and spread venom along and into the skin of the victim. The venom contains numerous chemical components, including neuromuscular toxins, cardiotoxins, hemolysins, dermonecrotoxins, and histamine-like compounds.
- II. **Toxic dose.** Each time a nematocyst is opened, all of the contained venom is released. The degree of effect will depend on the particular species, the number of nematocysts that successfully discharge venom, the envenomation site, contact time, and individual patient sensitivity (especially in children). Hundreds of thousands of nematocysts may be discharged with a single exposure.
 - A. Deaths from jellyfish stings in the Northern Hemisphere are rare and almost always due to the **Portuguese man-o-war** (*Physalia* sp), though *Chironex quadrumanus* (a type of box jellyfish) was implicated in the death of a child off the coast of Texas.
 - B. The **Australian box jellyfish** (*Chironex fleckeri*, AKA “sea wasp”) is the most venomous marine animal and is responsible for numerous fatalities. It should not be confused with the Hawaiian box jellyfish (*Carybdea alata*).
- III. **Clinical presentation**
 - A. **Acute effects.** Immediately upon nematocyst discharge, there is stinging, burning pain and a pruritic rash. Depending on the degree of envenomation,

there may follow paresthesias, anaphylactoid symptoms, hypotension, muscle spasm, local edema and hemolysis, local and even distal erythematous papular lesions proceeding to pustules and desquamation, chills, fever, nausea, vomiting, abdominal pain, diarrhea, transient elevated liver transaminases, myalgias, arthralgias, headache, anxiety, diaphoresis, pallor, cyanosis, dysphonia, ataxia, paralysis, coma, seizures, pulmonary edema, and cardiac arrhythmias. Lethal outcomes are associated with rapid onset of cardiovascular collapse. Fulminant hepatic failure and renal failure have been reported after sea anemone stings.

- B. Potential sequelae** include erythema multiforme, keloids, infections, cosmetic tissue damage (fat atrophy and hyperpigmentation), contractures, paresthesias, neuritis, recurrent cutaneous eruptions, paralysis, and regional vasospasm with vascular insufficiency.
- C. Corneal stings** from the sea nettle are usually painful but resolve within 1–2 days. However, there are reports of prolonged iritis, elevated intraocular pressure, mydriasis, and decreased visual acuity lasting months to years.
- IV. Diagnosis** is based on the history and observation of characteristic lines of inflammation along the sites of exposure (“tentacle tracks”).
 - A. Specific levels.** Specific toxin levels are not available.
 - B. Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, CPK, liver transaminases, and urinalysis for hemoglobin.
- V. Treatment.** Symptomatic care is sufficient for the majority of envenomations, even that of the box jellyfish.
 - A. Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Treat hypotension (see p 16), arrhythmias (pp 10–15), coma (p 19), and seizures (p 22) if they occur.
 - B. Specific drugs and antidotes.** Box jellyfish (*Chironex fleckeri*) antivenin from Australia terminates acute pain and cardiovascular symptoms, prevents tissue effects, and may be located by a regional poison control center (in the United States, [800] 222-1222) for use in severe cases. Local marine biologists can help identify indigenous species for planning of specific therapy.
 - C. Decontamination.** Avoid thrashing about, scratching, scraping, or other mechanical maneuvers that may break open the nematocysts. Without touching the affected areas, wash them with cold sea or salt water. **Do not use fresh water** because it may cause nematocysts to discharge.
 1. **For most cnidarian envenomations** (including the box jellyfish), experts recommend spraying, soaking, or flooding the affected area with **vinegar** for 30 minutes to disarm nematocysts. Other remedies for neutralizing nematocysts include rubbing alcohol, household ammonia, or a slurry of meat tenderizer or baking soda. (One even recommended urinating on the area if these agents are not available.) **Note:** None of these remedies relieves the pain of already discharged nematocysts, and may actually worsen it.
 2. However, for *Chrysaora quinquecirrha* (American sea nettle), *Pelagia noctiluca* (little mauve stinger jellyfish), and *Cyanea capillata* (hair or “lion’s mane” jellyfish), **do not apply vinegar** because it may precipitate firing in these species; instead, apply a slurry of **baking soda** for 10 minutes.
 3. Once disarmed, the nematocysts can be removed manually (use doubled-gloved hands or forceps) followed by shaving the area. Afterward, cool compresses may be applied for pain relief.
 - D. Enhanced elimination.** These procedures are not applicable.

O'Reilly GM et al: Prospective study of jellyfish stings from tropical Australia, including the major box jellyfish *Chironex fleckeri*. *Med J Aust* 2001;175(11–12):652–655. [PMID: 11837877] (Review of causes and clinical courses of 40 patients with jellyfish stings—mostly *C fleckeri*—presenting to a hospital in tropical Australia. None of the cases was severe and none required antivenom.)

► LEAD

Michael J. Kosnett, MD, MPH

Lead is a soft, malleable metal that is chiefly obtained by the primary smelting and refining of natural ores, or by the widespread practice of recycling and secondary smelting of scrap lead products. Recycling accounts for nearly 80% of domestic lead consumption, 90% of which is used in the manufacture of lead acid batteries. Lead is used for weights and radiation shielding, and lead alloys are used in the manufacture of pipes; cable sheathing; brass, bronze, and steel; ammunition; and solder (predominantly electrical devices and automotive radiators). Lead compounds are added as pigments, stabilizers, or binders in paints, ceramics, glass, and plastic.

Although the use of lead in house paint has been curtailed since the 1970s, industrial use of corrosion-resistant, lead-based paint continues, and high-level exposure may result from renovation, sandblasting, torching, or demolition. Young children are particularly at risk from repeated ingestion of lead-contaminated house dust, yard soil, or paint chips. Lead exposure may also occur from the use of lead-glazed ceramics or containers for food or beverage preparation or storage.

Certain folk medicines (eg, the Mexican remedies *azarcon* and *greta*, and some Indian Ayurvedic preparations) may contain high amounts of lead salts.

I. Mechanism of toxicity

- A. The multisystem toxicity of lead is mediated by several mechanisms, including inactivation or alteration of enzymes and other macromolecules by binding to sulfhydryl, phosphate, or carboxyl ligands, and interaction with essential cations, most notably calcium, zinc, and iron. Pathological alterations in cellular and mitochondrial membranes, neurotransmitter synthesis and function, heme synthesis, cellular redox status, and nucleotide metabolism may occur. Adverse impacts on the nervous, renal, hematopoietic, reproductive, and cardiovascular systems can result.
- B. **Pharmacokinetics.** Inhalation of lead fume or other fine, soluble particulate results in rapid and extensive pulmonary absorption, the major, though not exclusive route of exposure in industry. Nonindustrial exposure occurs predominantly by ingestion, particularly in children, who absorb 45–50% of soluble lead compared to approximately 10–15% in adults. Following absorption, lead is distributed via the blood (where 99% is bound to the erythrocyte) to multiple tissues, including transplacental transport to the fetus, and central nervous system transport across the blood-brain barrier. Clearance of lead from the body follows a multicompartiment kinetic model, consisting of “fast” compartments in the blood and soft tissues (half-life of 1 to 2 months) and slow compartments in the bone (half-life of years to decades). Greater than 90% of lead burden in adults and more than two-thirds of the burden of young children occur in the skeleton. Slow redistribution of lead from bone to soft tissues may elevate blood lead concentrations for months to years after a patient with chronic high-dose exposure has been removed from external sources. In patients with high bone lead burden, pathological states associated with rapid bone turnover or demineralization, such as hyperthyroidism or immobilization osteoporosis, have resulted in symptomatic lead intoxication.

II. Toxic dose

- A. **Dermal** absorption is minimal with inorganic lead, but may be substantial with organic lead compounds, which may also cause skin irritation.
- B. **Ingestion.** In general, absorption of lead compounds is directly proportional to solubility, and inversely proportional to particle size. Gastrointestinal lead absorption is increased by iron deficiency and low dietary calcium, and decreased by co-ingestion with food.
 1. Acute symptomatic intoxication is rare after a single exposure, but may occur within hours after ingestion of gram quantities of soluble lead compounds, or days after gastrointestinal retention of swallowed lead objects, such as fishing weights or curtain weights.

2. Studies have not established a low-dose threshold for adverse, subclinical effects of lead. Recent epidemiological studies in children have observed effects of lead on cognitive function at blood lead concentrations less than 5 mcg/dL, and other studies suggest that background levels of lead exposure in recent decades may have been associated with hypertension in some adults. The geometric mean blood lead concentration in the United States in 1999 was estimated to be 1.6 mcg/dL; background dietary lead intake may be in the range of 1–4 mcg per day.
 3. The US Environmental Protection Agency (EPA) action level for lead in drinking water is 15 ppb (parts per billion).
- C. Inhalation.** Unprotected exposure to the massive airborne lead levels (> 2500 mcg/m³) encountered during abrasive blasting, welding, or torch cutting metal surfaces coated with lead-based paint poses an acute hazard, and has resulted in symptomatic lead intoxication from within a day to a few weeks. The OSHA workplace permissible exposure limit (PEL) for inorganic lead dusts and fumes is 50 mcg/m³ as an 8-hour time-weighted average. The level considered immediately dangerous to life or health (IDLH) is 100 mg/m³.
- III. Clinical presentation.** The multisystem toxicity of lead presents a spectrum of clinical findings ranging from overt, life-threatening intoxication to subtle, subclinical effects.
- A. Acute ingestion** of very large amounts of lead (gram quantities) may cause abdominal pain, anemia (usually hemolytic), toxic hepatitis, and encephalopathy.
- B. Subacute or chronic exposure** is more common than acute poisoning.
1. **Constitutional** effects include fatigue, malaise, irritability, anorexia, insomnia, weight loss, decreased libido, arthralgias, and myalgias. Hypertension may be associated with lead exposure in susceptible populations.
 2. **Gastrointestinal** effects include crampy abdominal pain (lead colic), nausea, constipation, or (less commonly) diarrhea.
 3. **Central nervous system** manifestations range from impaired concentration, headache, diminished visual-motor coordination, and tremor to overt encephalopathy (a life-threatening emergency characterized by agitated delirium or lethargy, ataxia, convulsions, and coma). Chronic low-level exposure in infants and children may lead to decreased intelligence and impaired neurobehavioral development, stunted growth, and diminished auditory acuity.
 4. **Peripheral motor neuropathy**, affecting mainly the upper extremities, can cause severe extensor muscle weakness (“wrist drop”).
 5. **Hematologic** effects include normochromic or microcytic anemia, which may be accompanied by basophilic stippling. Hemolysis may occur.
 6. **Nephrotoxic** effects include reversible acute tubular dysfunction (including Fanconi-like aminoaciduria in children) and chronic interstitial fibrosis. Hyperuricemia and gout may occur.
 7. **Adverse reproductive outcomes** may include diminished or aberrant sperm production, increased rate of miscarriage, preterm delivery, decreased gestational age, low birth weight, and impaired neurologic development.
- C. Repeated, intentional inhalation of leaded gasoline** has resulted in ataxia, myoclonic jerking, hyperreflexia, delirium, and convulsions.
- IV. Diagnosis.** Although overt encephalopathy or abdominal colic associated with a suspect activity may readily suggest the diagnosis of severe lead poisoning, the nonspecific symptoms and multisystem signs associated with mild or moderate intoxication may be mistaken for a viral illness or other disorder. Consider lead poisoning in any patient with multisystem findings including abdominal pain, headache, and anemia, and less commonly, motor neuropathy, gout, and renal insufficiency. Consider lead encephalopathy in any child or adult with delirium or convulsions (especially with coexistent anemia), and chronic lead poisoning in any child with neurobehavioral deficits or developmental delays.

A. Specific levels. The **whole-blood lead** level is the most useful indicator of lead exposure. Relationships between blood lead levels and clinical findings have generally been based on subacute or chronic exposure and not on transiently high values that may result immediately after acute exposure. In addition, there may be considerable interindividual variability. **Note:** *Blood lead samples must be drawn and stored in lead-free syringes and tubes* ("trace metals" tube or royal blue stopper tube containing heparin or EDTA).

1. Blood lead levels are less than 5 mcg/dL in populations without occupational or specific environmental exposure. Levels between 5 (or lower) and 25 mcg/dL have been associated with subtle decreases in intelligence and impaired neurobehavioral development in children exposed in utero or in early childhood, but these levels are generally without demonstrable effects in adults.
2. Blood lead levels of 25–60 mcg/dL may be associated with headache, irritability, difficulty concentrating, slowed reaction time, and other neuropsychiatric effects. Anemia may occur, and subclinical slowing of motor nerve conduction may be detectable.
3. Blood levels of 60–80 mcg/dL may be associated with gastrointestinal symptoms and subclinical renal effects.
4. With blood levels in excess of 80 mcg/dL, serious overt intoxication may occur, including abdominal pain (lead colic) and nephropathy. Encephalopathy and neuropathy are usually associated with levels over 100 mcg/dL.

B. Elevations in free erythrocyte protoporphyrin (FEP) or zinc protoporphyrin (ZPP) (> 35 mcg/dL) reflect lead-induced inhibition of heme synthesis. Because only actively forming and not mature erythrocytes are affected, elevations will typically lag lead exposure by a few weeks. A high blood lead in the presence of a normal FEP or ZPP therefore suggests very recent exposure. Protoporphyrin elevation is not specific for lead, and may also occur with iron deficiency. Protoporphyrin levels are not sensitive for low-level exposure (blood lead < 30 mcg/dL).

C. Urinary lead excretion increases and decreases more rapidly than blood lead. Normal urinary lead excretion is less than 50 mcg/day. Several empiric protocols that measure 6- or 24-hour urinary lead excretion after calcium EDTA challenge have been developed to identify persons with elevated body lead burdens. However, since chelatable lead predominantly reflects lead in soft tissues, which in most cases already correlates satisfactorily with blood lead, chelation challenges are seldom indicated in clinical practice.

D. Noninvasive in vivo x-ray fluorescence measurement of lead in bone, a test predominantly available in research settings, may provide the best index of long-term cumulative lead exposure and total body lead burden.

E. Other tests. Nonspecific laboratory findings that support the diagnosis of lead poisoning include anemia (normocytic or microcytic), and basophilic stippling of erythrocytes, a useful but insensitive clue. Acute high-dose exposure may sometimes be associated with transient azotemia (elevated BUN and serum creatinine) and mild to moderate elevation in serum transaminases. Recently ingested lead paint, glazes, chips, or solid lead objects may be visible on abdominal x-rays. CT or MRI of the brain often reveals cerebral edema in patients with lead encephalopathy. Because iron deficiency increases lead absorption, iron status should be evaluated.

V. Treatment

A. Emergency and supportive measures

1. Treat seizures (see p 22) and coma (p 19) if they occur. Provide adequate fluids to maintain urine flow (optimally 1–2 mL/kg/h) but avoid overhydration, which may aggravate cerebral edema. Avoid phenothiazines for delirium, as they may lower the seizure threshold.
2. Patients with increased intracranial pressure may benefit from corticosteroids (eg, dexamethasone, 10 mg IV) and mannitol (1–2 g/kg IV).

B. Specific drugs and antidotes. Treatment with chelating agents decreases blood lead concentrations and increases urinary lead excretion. Although

chelation has been associated with improvement in symptoms and decreased mortality, controlled clinical trials demonstrating efficacy are lacking, and *treatment recommendations have been largely empiric.*

1. **Encephalopathy.** Administer intravenous **calcium EDTA** (see p 440). Some clinicians initiate treatment with a single dose of **BAL** (p 413), followed 4 hours later by concomitant administration of calcium EDTA and BAL.
 2. **Symptomatic without encephalopathy.** Administer oral **succimer** (DMSA, p 501) or parenteral **calcium EDTA** (p 440). Calcium EDTA is preferred as initial treatment if the patient has severe gastrointestinal toxicity (eg, lead colic) or if the blood lead concentration is extremely elevated (eg >150 mcg/dL). **Unithiol** (p 506) may be considered as an alternative to DMSA.
 3. **Asymptomatic children with elevated blood lead levels.** The Centers for Disease Control and Prevention (CDC) recommend treatment of children with levels of 45 mcg/dL or higher. Use oral **succimer** (DMSA, p 501). A recent large randomized, double-blind, placebo-controlled trial of DMSA in children with blood lead concentrations between 25 and 44 mcg/dL found no evidence of clinical benefit.
 4. **Asymptomatic adults.** The usual treatment is removal from exposure and observation. Consider oral **succimer** (DMSA, p 501) for patients with markedly elevated levels (eg, > 80–100 mcg/dL).
 5. Although **d-penicillamine** (see p 484) is an alternative oral treatment, it may be associated with more side effects and less efficient lead diuresis.
 6. **Blood lead monitoring during chelation.** Obtain a blood lead measurement immediately prior to chelation and recheck the measurement within 24–48 hours after starting chelation to confirm that levels are declining. Recheck measurements 1 and 7 to 21 days postchelation to assess the extent of rebound in blood lead level associated with redistribution of lead from high bone stores, and/or the possibility of reexposure. Additional courses of treatment and further investigation of exposure sources may be warranted.
- C. Decontamination** (see p 47)
1. **Acute ingestion.** Because even small items (eg, a paint chip or a sip of lead-containing glaze) may contain several hundred milligrams of lead, gut decontamination is indicated after acute ingestion of virtually any lead-containing substance.
 - a. Administer activated charcoal (although efficacy is unknown).
 - b. If lead-containing material is still visible on abdominal x-ray after initial treatment, consider whole-bowel irrigation (see p 52).
 - c. Consider endoscopic or surgical removal of lead foreign bodies that exhibit prolonged gastrointestinal retention.
 2. **Lead-containing buckshot, shrapnel, or bullets** in or adjacent to synovial spaces should be surgically removed if possible, particularly if associated with evidence of systemic lead absorption.
- D. Enhanced elimination.** There is no role for dialysis, hemoperfusion, or repeat-dose charcoal.
- E. Other required measures.** Remove the patient from the source of exposure, and institute control measures to prevent repeated intoxication. Other possibly exposed persons (eg, coworkers, or siblings or playmates of young children) should be promptly evaluated.
1. **Infants and children.** The CDC has recommended universal blood lead screening of children at 12 and 24 months of age in communities where >27% of dwellings were constructed prior to 1950. For other communities, screening targeted to children from families with low income or other selected risk factors is recommended. General management guidelines are based on the results of the blood lead test:
 - a. 10–14 mcg/dL: repeat screening; educate parents about risk factors.
 - b. 15–19 mcg/dL: repeat screening, and if elevated, refer for public health case management to investigate and abate sources.

- c. 20–44 mcg/dL: perform complete medical evaluation; refer for case management.
 - d. 45–69 mcg/dL: perform complete medical evaluation; chelate with oral succimer, refer for case management.
 - e. 70 mcg/dL or higher: hospitalize child for immediate chelation; refer for case management.
 - f. Detailed guidelines for case management of children with elevated blood lead levels are found at the CDC website: www.cdc.gov/nceh/lead/CaseManagement/caseManage_main.htm
- 2. Adults with occupational exposure**
- a. Federal OSHA standards for workers exposed to lead provide specific guidelines for periodic blood lead monitoring and medical surveillance (see www.osha-slc.gov/OshStd_toc/OSHA_Std_toc_1910.html). Under the general industry standard, workers must be removed from exposure if a single blood lead level exceeds 60 mcg/dL or if the average of three successive levels exceeds 50 mcg/dL. In construction workers, removal is required if a single blood lead level exceeds 50 mcg/dL. Workers may not return to work until the blood lead level is below 40 mcg/dL and any clinical manifestations of toxicity have resolved. Prophylactic chelation is prohibited. OSHA standards mandate that workers removed from work because of elevated blood lead levels retain full pay and benefits.
 - b. Medical removal parameters in the OSHA standards summarized above were established in the late 1970s, and are outdated based on current background blood levels and recent concern over the hazards of lower-level exposure. The standards explicitly empower physicians to order medical removal at lower blood lead levels. It may now be prudent and feasible for employers to maintain workers' blood lead levels below 20 mcg/dL.

Lanphear BP et al: Cognitive deficits associated with blood lead concentrations < 10 mcg/dL in US children and adolescents. *Publ Health Rep* 2000;115:521–529. [PMID: 11354334] (Data in the large NHANES III study associate blood lead levels less than 5 mcg/dL with cognitive deficits in children.)

Rogan WJ et al: The effect of chelation therapy with succimer on neuropsychological development in children exposed to lead. *N Engl J Med* 2001;344:1421–1426. [PMID: 11346806] (A randomized, double-blind, placebo-controlled trial of succimer in children with blood lead levels 20–44 mcg/dL showed no benefit of chelation on cognitive function or long-term blood lead reduction.)

► LIONFISH AND OTHER SCORPAENIDAE

Richard F. Clark, MD

The family Scorpaenidae are saltwater fish that are mostly bottom dwellers, noted for their ability to camouflage themselves and disappear into the environment. There are 30 genera and about 300 species, some 30 of which have envenomated humans. Although they were once considered to be an occupational hazard only of commercial fishing, increasing contact with these fish by scuba divers and home aquarists has increased the frequency of envenomations.

- I. Mechanism of toxicity.** Envenomation usually occurs when the fish is being handled or stepped on or when the aquarist has hands in the tank. The dorsal, anal, and pectoral fins are supported by spines that are connected to venom glands. The fish will erect its spines and jab the victim, causing release of venom (and often sloughing of the integumentary sheath of the spine into the wound). The venom of all these organisms is a heat-labile mixture that is not completely characterized.

- II. Toxic dose.** The dose of venom involved in any sting is variable. Interspecies variation in the severity of envenomation is generally the result of the relation between the venom gland and the spines.
- A. *Synanceja*** (Australian stonefish) have short, strong spines with the venom gland located near the tip; therefore, large doses of venom are delivered and severe envenomation results.
- B. *Pterois*** (lionfish, turkeyfish) have long delicate spines with poorly developed venom glands near the base of the spine and therefore are usually capable of delivering only small doses of venom.
- III. Clinical presentation.** Envenomation typically produces immediate onset of excruciating, sharp, throbbing, intense pain. In untreated cases, the intensity of pain peaks at 60–90 minutes and may last for 1–2 days.
- A. Systemic intoxication** associated with stonefish envenomation can include the rapid onset of hypotension, tachycardia, cardiac arrhythmias, myocardial ischemia, syncope, diaphoresis, nausea, vomiting, abdominal cramping, dyspnea, pulmonary edema, cyanosis, headache, muscular weakness, and spasticity.
- B. Local tissue effects** include erythema, ecchymosis, and swelling. Infection may occur owing to retained portions of integumentary sheath. Hyperalgesia, anesthesia, or paresthesias of the affected extremity may occur, and persistent neuropathy has been reported.
- IV. Diagnosis** is usually based on a history of exposure, and the severity of envenomation is usually readily apparent.
- A. Specific levels.** There are no specific toxin levels available.
- B. Other useful laboratory studies** for severe intoxication include electrolytes, glucose, BUN, creatinine, CPK, urinalysis, ECG monitoring, and chest x-ray.
- V. Treatment**
- A. Emergency and supportive measures**
1. After severe stonefish envenomation:
 - a. Maintain an open airway and assist ventilation if needed (see pp 1–7). Administer supplemental oxygen.
 - b. Treat hypotension (see p 16) and arrhythmias (pp 10–15) if they occur.
 2. General wound care:
 - a. Clean the wound carefully and remove any visible integumentary sheath. Monitor wounds for development of infection.
 - b. Give tetanus prophylaxis if needed.
- B. Specific drugs and antidotes.** Immediately immerse the extremity in **hot water** (45°C or 113°F) for 30–60 minutes. This should result in prompt relief of pain within several minutes. For stonefish envenomations, a specific antivenin can be located by a regional poison control center (in the United States, [800] 222-1222), but most of these cases can be successfully managed with hot water immersion and supportive symptomatic care.
- C. Decontamination** procedures are not applicable.
- D. Enhanced elimination.** There is no role for these procedures.

Burnett JW: Aquatic antagonists: lionfish stings. *Cutis* 2001;68(1):19–20. [PMID: 11480140] (Review.)

► LITHIUM

Michael A. Miller, MD, and Neal L. Benowitz, MD

Lithium is used for the treatment of bipolar depression and other psychiatric disorders and occasionally to boost the white blood cell count in patients with leukopenia. Serious toxicity is most commonly caused by chronic overmedication in patients with renal impairment. Acute overdose, in contrast, is generally less severe.

I. Mechanism of toxicity

A. Lithium is a cation that enters cells and substitutes for sodium or potassium. Lithium is thought to stabilize cell membranes. With excessive levels, it depresses neural excitation and synaptic transmission.

B. Pharmacokinetics. Lithium is completely absorbed within 6–8 hours of ingestion. The initial volume of distribution (Vd) is about 0.5 L/kg, with slow entry into tissues and a final Vd of 0.7–0.9 L/kg. Entry into the brain is slow, which explains the delay between peak blood levels and central nervous system (CNS) effects after an acute overdose. Elimination is virtually entirely by the kidney, with a half-life of 14–30 hours.

II. Toxic dose. The usual daily dose of lithium ranges from 300 to 2400 mg (8–64 mEq/day), and the therapeutic serum lithium level is 0.6–1.2 mEq/L. The toxicity of lithium depends on whether the overdose is acute or chronic.

A. Acute ingestion of 1 mEq/kg (40 mg/kg) will produce a blood level after tissue equilibration of approximately 1.2 mEq/L. Acute ingestion of more than 20–30 tablets by an adult would potentially cause serious toxicity.

B. Chronic intoxication may occur in patients on stable therapeutic doses. Lithium is excreted by the kidney, where it is handled like sodium; any state that causes dehydration, sodium depletion, or excessive sodium reabsorption may lead to increased lithium reabsorption, accumulation, and possibly intoxication. Common states causing lithium retention include acute gastroenteritis, diuretic use, use of nonsteroidal anti-inflammatory drugs or angiotensin-converting enzyme (ACE) inhibitors, and lithium-induced nephrogenic diabetes insipidus.

III. Clinical presentation. Mild to moderate intoxication results in lethargy, muscular weakness, slurred speech, ataxia, tremor, and myoclonic jerks. Rigidity and extrapyramidal effects may be seen. Severe intoxication may result in agitated delirium, coma, convulsions, and hyperthermia. Recovery is often very slow, and patients may remain confused or obtunded for several days to weeks. Rarely, cerebellar and cognitive dysfunction are persistent. Cases of rapidly progressive dementia, similar to Jacob-Creutzfeldt disease, have occurred and are usually reversible. The ECG commonly shows T-wave inversions; less commonly, bradycardia and sinus node arrest may occur. The white cell count is often elevated ($15\text{--}20,000/\text{mm}^3$).

A. Acute ingestion may cause initial mild nausea and vomiting, but systemic signs of intoxication are minimal and usually are delayed for several hours while lithium distributes into tissues. Initially high serum levels fall by 50–70% or more with tissue equilibration.

B. In contrast, patients with **chronic intoxication** usually already have systemic manifestations on admission, and toxicity may be severe with levels only slightly above therapeutic. Typically, patients with chronic intoxication have elevated BUN and creatinine levels and other evidence of dehydration or renal insufficiency.

C. Nephrogenic diabetes insipidus (see p 35) is a recognized complication of chronic lithium therapy and may lead to dehydration and hypernatremia.

IV. Diagnosis. Lithium intoxication should be suspected in any patient with a known psychiatric history who is confused, ataxic, or tremulous.

A. Specific levels. The diagnosis is supported by an elevated **lithium** level.

1. Most hospital clinical laboratories can perform a stat serum lithium concentration. However, the serum lithium level is not an accurate predictor of toxicity.

a. With chronic poisoning, toxicity may be associated with levels only slightly above the therapeutic range.

b. On the other hand, peak levels as high as 9.3 mEq/L have been reported early after acute ingestion without signs of intoxication, owing to measurement before final tissue distribution.

c. Note: Specimens obtained in a green-top tube (lithium heparin) will give a markedly false elevation of the serum lithium level.

2. Cerebrospinal fluid lithium levels higher than 0.4 mEq/L were associated in one case report with CNS toxicity.

B. Other useful laboratory studies include electrolytes (the anion gap may be narrowed owing to elevated chloride or bicarbonate), glucose, BUN, creatinine, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. In obtunded patients, maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat coma (see p 19), seizures (p 22), and hyperthermia (p 21) if they occur.
3. In dehydrated patients, replace fluid deficits with intravenous crystalloid solutions. Initial treatment should include repletion of sodium and water with 1–2 L of normal saline (children: 10–20 mL/kg). Once fluid deficits are replaced, give hypotonic (eg, half-normal saline) solutions because continued administration of normal saline often leads to hyponatremia, especially in patients with lithium-induced nephrogenic diabetes insipidus.

B. Specific drugs and antidotes. There is no specific antidote. Thiazides and indomethacin have been used for treatment of nephrogenic diabetes insipidus (see p 35).

C. Decontamination (see p 46) measures are appropriate after acute ingestion but not chronic intoxication.

1. **Prehospital.** Consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Consider gastric lavage for large recent ingestion. Activated charcoal does not adsorb lithium but may be useful if other drug ingestion is suspected.
3. Whole-bowel irrigation (see p 52) may enhance gut decontamination, especially in cases involving sustained-release preparations that are not likely to dissolve readily during the lavage procedure.
4. Oral administration of sodium polystyrene sulfonate (SPS, Kayexalate) has been advocated to attempt to reduce lithium absorption, but there is insufficient evidence of safety or effectiveness.

D. Enhanced elimination (see p 54). Lithium is excreted exclusively by the kidneys. The clearance is about 25% of the glomerular filtration rate and is reduced by sodium depletion or dehydration.

1. **Hemodialysis** removes lithium effectively and is indicated for intoxicated patients with seizures or severely abnormal mental status and for patients unable to excrete lithium renally (ie, anephric or anuric patients). Repeated and prolonged dialysis may be necessary because of slow movement of lithium out of the CNS.
2. **Continuous venovenous hemodiafiltration** has been shown to be effective in removing lithium in several human cases.
3. Forced diuresis only slightly increases lithium excretion compared with normal hydration and is not recommended. However, establishing normal urine output may bring the urinary lithium clearance to 25–30 mL/min.
4. Oral sodium polystyrene sulfonate (SPS, Kayexalate) enhances elimination of lithium in animal models, but there is insufficient experience in humans.
5. Hemoperfusion and repeat-dose charcoal are not effective.

Meyer RJ et al: Hemodialysis followed by continuous hemofiltration for treatment of lithium intoxication in children. *Am J Kidney Dis* 2001;37(5):1044–1047. [PMID: 11325688] (The authors argue that CVVH can reduce rebound in lithium levels after dialysis.)

Nagappan R et al: Acute lithium intoxication. *Anaesth Intensive Care* 2002;30(1):90–92. [PMID: 11939450] (A 51-year-old woman had a peak level of 10.6 mEq/L at 13 hours after acute

lithium overdose and a repeat level of 5.8 at 24 hours. She recovered with IV fluids and without hemodialysis.)

► LOMOTIL AND OTHER ANTIDIARRHEALS

Ilene B. Anderson, PharmD

Lomotil is a combination product containing diphenoxylate and atropine that is commonly prescribed for symptomatic treatment of diarrhea. Children are especially sensitive to small doses of Lomotil and may develop delayed toxicity after accidental ingestion. **Motofen** is a similar drug which contains difenoxin and atropine. **Loperamide** (Imodium™) is a nonprescription drug with similar properties.

I. Mechanism of toxicity

- A. **Diphenoxylate** is an opioid analog of meperidine. It is metabolized to **difenoxin**, which has fivefold the antidiarrheal activity of diphenoxylate. Both agents have opioid effects (see p 286) in overdose.
- B. **Atropine** is an anticholinergic agent (see p 84) that may contribute to lethargy and coma. It also slows drug absorption and may delay the onset of symptoms.
- C. **Loperamide** is a synthetic piperidine derivative structurally similar to diphenoxylate and haloperidol. It may produce opioid-like toxicity in overdose.

II. Toxic dose

- A. **Lomotil™**. The toxic dose is difficult to predict because of wide individual variability in response to drug effects and promptness of treatment. The lethal dose is unknown, but death in children has been reported after ingestion of **fewer than five tablets**.
- B. **Loperamide**. A single acute ingestion of less than 0.4 mg/kg is not likely to cause serious toxicity in children over 1 year of age. Fatalities, abdominal distention, and paralytic ileus have been reported in children under 1 year of age after ingestion of 0.6–3 mg per day.

III. Clinical presentation.

Depending on the individual and the time since ingestion, manifestations may be of primarily anticholinergic or opioid intoxication.

- A. **Atropine** intoxication may occur before, during, or after opioid effects. Anticholinergic effects include lethargy or agitation, flushed face, dry mucous membranes, mydriasis (dilated pupils), ileus, hyperpyrexia, and tachycardia.
- B. **Opioid intoxication** produces small pupils, coma, and respiratory arrest, and the onset of these effects is often delayed for several hours after ingestion.
- C. All the antidiarrheals may cause vomiting, abdominal distention, and paralytic ileus.

IV. Diagnosis

is based on the history and signs of anticholinergic or opioid intoxication.

- A. **Specific levels**. Specific serum levels are not available.
- B. **Other useful laboratory studies** include electrolytes, glucose, and arterial blood gases (if respiratory insufficiency is suspected).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19) and hypotension (p 16) if they occur.
3. Because of the danger of abrupt respiratory arrest, observe all children with Lomotil™ or Motofen™ ingestion in an intensive care unit for 18–24 hours. Similar precautions should be taken for patients with very large ingestions of loperamide.

B. Specific drugs and antidotes

1. Administer **naloxone**, 1–2 mg IV (see p 469), to patients with lethargy, apnea, or coma. Repeated doses of naloxone may be required, because its duration of effect (1–2 hours or less) is much shorter than that of the opioids in these products.

2. There is no evidence that **physostigmine** (see p 489) is beneficial for this overdose, although it may reverse signs of anticholinergic poisoning.
- C. **Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting because of the risk for unpredictable onset of coma.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary after a small ingestion if activated charcoal can be given promptly.
- D. **Enhanced elimination.** There is no role for these procedures.

Litovitz T et al: Surveillance of loperamide ingestions: an analysis of 216 poison center reports. *J Toxicol Clin Toxicol* 1997;35(1):11–19. [PMID: 9022646] (Drowsiness, vomiting and abdominal pain were the most frequent symptoms. There were no life-threatening symptoms and no deaths. The authors recommend home observation without decontamination for ingestion of less than 0.4 mg/kg.)

► LYSERGIC ACID DIETHYLAMIDE (LSD) AND OTHER HALLUCINOGENS

Manish Patel, MD

Patients seeking medical care after self-administering mind-altering substances may have used any of a large variety of chemicals. Several of these agents are discussed elsewhere in this manual (eg, amphetamines [p 72], cocaine [p 171], marijuana [p 252], phencyclidine [p 300], and toluene [p 357]). The drugs discussed in this section, LSD and other hallucinogens, have become known in some circles as *entactogens* (“to touch within”), and several have been widely used for personal experimentation as well as clinically to facilitate psychotherapeutic interviews. Table II–32 lists some common and uncommon hallucinogens.

- I. **Mechanism of toxicity.** Despite many intriguing theories and much current research, the biochemical mechanism of hallucinations is not known. LSD stimulates 5-HT₂ receptors, and many other agents are thought to alter the activity of serotonin and dopamine in the brain. Central and peripheral sympathetic stimulation may account for some of the side effects such as anxiety, psychosis, dilated pupils, and hyperthermia. Some agents (eg, MDMA) are directly neurotoxic.
- II. **Toxic dose.** The toxic dose is highly variable depending on the agent and the circumstances (see Table II–32). In general, entactogenic effects do not appear to be dose-related; therefore, increasing the dose does not intensify the desired effects. Likewise, paranoia or panic attacks may occur with any dose and depend on the surroundings and the patient’s current emotional state. On the other hand, hallucinations, visual illusions, and sympathomimetic side effects are dose-related. The toxic dose may be only slightly greater than the recreational dose. In human volunteers receiving recreational doses of MDMA, elimination was nonlinear, implying that small increases in dosing may increase the risk of toxicity.
- III. **Clinical presentation**
 - A. **Mild to moderate intoxication**
 1. The person experiencing a “bad trip” is conscious, coherent, and oriented but is anxious and fearful and may display paranoid or bizarre reasoning. The patient may also be tearful, combative, or self-destructive. Delayed intermittent “flashbacks” may occur after the acute effects have worn off and are usually precipitated by use of another mind-altering drug.
 2. The person with dose-related sympathomimetic side effects may also exhibit tachycardia, mydriasis (dilated pupils), diaphoresis, bruxism, short attention span, tremor, hyperreflexia, hypertension, and fever.
 - B. **Life-threatening toxicity**
 1. Intense sympathomimetic stimulation can cause seizures, severe hyperthermia, hypertension, intracranial hemorrhage and cardiac arrhythmias.

TABLE II-32. EXAMPLES OF HALLUCINOGENS

Drug or Compound	Common Name	Comments
5-Hydroxy- <i>N,N</i> -dimethyltryptamine	Bufofenine	From skin secretions of the toad <i>Bufo vulgaris</i> .
<i>N,N</i> -dimethyltryptamine	DMT	“Businessman’s trip”: short duration (30–60 minutes).
2,5-Dimethoxy-4-bromoamphetamine ^a	DOB	Potent ergot-like vascular spasm may result in ischemia, gangrene.
2,5-Dimethoxy-4-methylamphetamine ^a	DOM, STP	Potent sympathomimetic.
4,9-Dihydro-7-methoxy-1-methyl-3-pyrido(3,4)-indole	Harmaline	South American religious and cultural drink called yage or ayahuasca.
Lysergic acid diethylamide	LSD, acid	Potent hallucinogen. Average dose 50–150 mcg in tablets, papers.
<i>n</i> -Methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine	MBDB	Nearly pure entactogen without hallucinosis or sympathomimetic stimulation.
3,4-Methylenedioxy-amphetamine ^a	MDA	Potent sympathomimetic. Several hyperthermic deaths reported.
3,4-Methylenedioxy-methamphetamine ^a	MDMA, ecstasy, Adam	Sympathomimetic: hyperthermia, seizures, cerebral hemorrhage, and arrhythmias reported; hyponatremia.
3,4-Methylenedioxy- <i>n</i> -ethylamphetamine ^a	MDE, Eve	
3,4,5-Trimethoxyphenethylamine	Mescaline	Derived from peyote cactus.
3-Methoxy-4,5-methylene-dioxyallylbenzene	Myristicin, nutmeg	
<i>p</i> -Methoxyamphetamine ^a	PMA	Contaminant or adulterant in some pills sold as MDMA; potent sympathomimetic.
4-Phosphoryloxy- <i>N,N</i> -dimethyltryptamine	Psilocybin	From <i>Psilocybe</i> mushrooms.

^aAmphetamine derivatives. See also p 72.

Hyperthermic patients are usually obtunded, agitated or thrashing about, diaphoretic, and hyperreflexic. Untreated, hyperthermia may result in hypotension, coagulopathy, rhabdomyolysis, and hepatic and other organ failure (see p 21). Hyperthermia has been associated with LSD, methylene dioxyamphetamine (MDA), MDMA, and paramethoxyamphetamine (PMA).

2. Severe hyponatremia has been reported after use of MDMA, and may result from both excess water intake and inappropriate secretion of antidiuretic hormone.
3. Use of 2,5-dimethoxy-4-bromoamphetamine (DOB) has resulted in ergot-like vascular spasm, circulatory insufficiency, and gangrene (see p 189).

IV. Diagnosis is based on a history of use and the presence of signs of sympathetic stimulation. Diagnosis of hyperthermia requires a high level of suspicion and use of a thermometer that accurately measures core temperature (rectal, tympanic membrane, or esophageal probe).

A. Specific levels. Serum drug levels are neither widely available nor clinically useful in emergency management. The amphetamine derivatives (DOB, STP, MDA, MDMA, etc) cross-react in many of the available screening procedures for amphetamine class drugs. However, LSD and the other nonamphetamine hallucinogens listed in Table II-32 are not identified on routine toxicology screening. Recently, several LSD screening immunoassays have become available, although they are of limited use because of false-positive and false-negative results and a short window of detection (4–12 hours).

B. Other useful laboratory studies include electrolytes, glucose, BUN, and creatinine. In hyperthermic patients, obtain prothrombin time, CPK, and urinalysis dipstick for occult blood (myoglobinuria will be positive).

V. Treatment

A. For the patient with a “bad trip” or panic reaction, provide gentle reassurance and relaxation techniques in a quiet environment.

1. Treat agitation (see p 24) or severe anxiety states with diazepam or midazolam (p 415). Butyrophenones such as haloperidol (p 451) are useful despite a small theoretic risk of lowering the seizure threshold.
2. Treat seizures (see p 21), hyperthermia (p 21), rhabdomyolysis (p 27), hypertension (p 16), and cardiac arrhythmias (pp 10–15) if they occur.

B. Specific drugs and antidotes. There is no specific antidote. Sedating doses of diazepam (2–10 mg) may alleviate anxiety, and hypnotic doses (10–20 mg) can induce sleep for the duration of the “trip.”

C. Decontamination (see p 47). Most of these drugs are taken orally in small doses.

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because it is relatively ineffective and is likely to aggravate psychological distress. Moreover, some of the drugs can induce seizures.
2. **Hospital.** Administer activated charcoal. There is no need for gastric lavage, unless massive ingestion is suspected or the person is unable or unwilling to ingest the charcoal.

D. Enhanced elimination. These procedures are not useful. Although urinary acidification may increase the urine concentration of some agents, it does not significantly enhance total-body elimination and may aggravate myoglobinuric renal failure.

Kalant H: The pharmacology and toxicology of “ecstasy” (MDMA) and related drugs. *CMAJ* 2001;165(7):917–928. [PMID: 11599334] (Detailed review of MDMA fatalities reported in the literature.)

Kraner JC et al: Fatalities caused by the MDMA-related drug paramethoxyamphetamine (PMA). *J Anal Toxicol* 2001 Oct;25(7):645–648. [PMID: 11599617] (PMA has been found in some tablets sold as MDMA, and has caused hyperthermia, seizures, and death.)

► MAGNESIUM

Kathryn H. Meier, PharmD

Magnesium (Mg) is a divalent cation required for a variety of enzymatic reactions involving protein synthesis and carbohydrate metabolism. It is also an essential ion for proper neuromuscular functioning. Oral magnesium is widely available in over-the-counter antacids (eg, Maalox and Mylanta) and cathartics (milk of magnesia, magnesium citrate). Intravenous magnesium is used to treat toxemia of pregnancy, polymorphous ventricular tachycardia, refractory ventricular arrhythmias, and rarely, bronchospasm.

I. Mechanism of toxicity

- A. Elevated serum magnesium concentrations act as a CNS depressant and block neuromuscular transmission by inhibiting acetylcholine release at the motor endplate. Hypermagnesemia amplifies the response to neuromuscular blockers.
- B. Magnesium also antagonizes calcium channel function and intracellular calcium flux, impairing muscle contraction and electrical conduction.
- C. **Pharmacokinetics.** The usual body content of Mg is approximately 1700–2200 mEq in a 70-kg person; most is intracellular. The elimination half-life for a 104-mEq oral dose is approximately 4–5 hours in healthy adults. Normal kidney function is essential for clearance as 97% of ingested Mg is eliminated in the urine.

II. Toxic dose.

Only about 30% of orally administered magnesium is absorbed from the gastrointestinal tract, and excess magnesium is usually rapidly excreted by the kidneys. Hypermagnesemia rarely occurs after acute or chronic overexposure except in patients with renal insufficiency ($\text{CrCl} < 30 \text{ mL/min}$), or massive or intravenous overdose.

- A. Commonly available antacids (eg, Maalox, Mylanta, and others) contain 12.5–37.5 mEq of magnesium per 15 mL (one tablespoon), milk of magnesia contains about 40 mEq per 15 mL, and magnesium sulfate contains 8 mEq per g.
- B. Ingestion of 200 g of magnesium sulfate caused coma in a young woman with normal renal function.

III. Clinical presentation.

Orally administered magnesium causes diarrhea, usually within 3 hours. Repeated or excessive doses of magnesium-containing cathartics can cause serious fluid and electrolyte abnormalities. Moderate toxicity may cause nausea, vomiting, weakness, and cutaneous flushing. Larger doses can cause cardiac conduction abnormalities, hypotension, severe muscle weakness, and lethargy. Very high levels can cause coma, respiratory arrest, and asystole (see Table II–33).

IV. Diagnosis

should be suspected in a patient with renal insufficiency who presents with weakness or hypotonia, especially if there is a history of using magnesium-containing antacids or cathartics.

TABLE II–33. MAGNESIUM POISONING

Magnesium (mg/dL)	Magnesium (mEq/L)	Magnesium (mmol/L)	Possible clinical effects
> 3.5	> 3	> 1.5	Nausea, vomiting, weakness, cutaneous flushing
> 6	> 5	> 2.5	ECG changes—prolonged PR, QRS, QT intervals
8–12	7–10	3.5–5	Hypotension, loss of deep tendon reflexes, sedation
> 12	> 10	> 5	Muscle paralysis, respiratory arrest, hypotension, arrhythmias
> 17	> 14	> 7	Death from respiratory arrest or asystole

A. Specific levels. Determination of serum magnesium concentration is usually rapidly available. The normal range is 1.8–3.0 mg/dL (0.75–1.25 mmol/L, or 1.5–2.5 mEq/L) total Mg. Therapeutic levels for treatment of toxemia of pregnancy (eclampsia) are 5–7.4 mg/dL (2–3 mmol/L, or 4–6 mEq/L) total Mg. Ionized levels correlate with total Mg levels, and are not indicated.

B. Other useful laboratory studies include electrolytes, BUN, creatinine, serum osmolality and osmolar gap (magnesium may elevate the osmolar gap), calcium, and ECG.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Replace fluid and electrolyte losses caused by excessive catharsis.
3. Treat hypotension with intravenous fluids and dopamine (see p 16).

B. Specific drugs and antidotes. There is no specific antidote. Administration of intravenous **calcium** (see p 424) may temporarily alleviate respiratory depression.

C. Decontamination (see p 47)

1. **Prehospital.** Activated charcoal is not effective. If a delay of more than 60 minutes is expected before medical care can be obtained, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Consider gastric emptying with a nasogastric tube for large recent ingestions. Do **not** administer a cathartic. Activated charcoal is not effective.

D. Enhanced elimination

1. **Hemodialysis** rapidly removes magnesium, and is the only route of elimination in anuric patients.
2. Hemoperfusion and repeat-dose charcoal are not effective.
3. Forced diuresis using intravenous furosemide and normal saline may enhance Mg elimination, but there is insufficient human data to recommend it.

Birrer RB et al: Hypermagnesemia-induced fatality following epsom salt gargles. *J Emerg Med* 2002;22(2):185–188. [PMID: 11858925] (Fatal case with Mg level of 23.6 mg/dL [9.8 mmol/L] and coma.)

Harker HE, Majcher TA: Hypermagnesemia in a pediatric patient. *Anesth Analg* 2000;91(5):1160–1162. [PMID: 11049902] (Accidental iatrogenic overdose during surgery in an 18-month-old girl.)

► MANGANESE

Paul D. Blanc, MD, MSPH

Manganese intoxication is generally caused by chronic rather than acute exposure. Sources of exposure are almost universally industrial—mining, metal working, smelting, foundries, and welding. Recent studies also suggest a possible link between an organic manganese fungicide (Maneb) and chronic neurologic toxicity. A gasoline additive, methylcyclopentadienyl manganese tricarbonyl (MMT), has been promoted for combustion efficiency but creates potential health concerns.

- I. Mechanism of toxicity.** The precise mechanism is not known. The central nervous system is the target organ.
- II. Toxic dose.** The primary route of exposure is inhalation; inorganic manganese is poorly absorbed from the gastrointestinal tract. The OSHA workplace permissible exposure limit (PEL) for manganese dust is 5 mg/m³. The air level considered to be immediately dangerous to life or health (IDLH) is 10,000 ppm.
- III. Clinical presentation.** Acute high-level manganese inhalation can produce an irritant-type pneumonitis (see p 213). More typically, toxicity occurs after chronic

exposure to low levels over months or years. The patient usually presents with a psychiatric disorder, frequently misdiagnosed as schizophrenia or atypical psychosis. Organic signs of neurologic toxicity, such as parkinsonism or other extrapyramidal movement disorders, usually appear later, some time after a primarily psychiatric presentation.

IV. Diagnosis depends on a thorough occupational and psychiatric history.

A. Specific levels. Testing of whole blood, serum, or urine may be performed, but the results should be interpreted with caution, as they may not correlate with clinical effects. Whole-blood levels are 20 times greater than serum or plasma, and red blood cell contamination can falsely elevate serum or plasma levels.

1. Normal serum manganese concentrations are usually less than 1.2 mcg/L.
2. Elevated urine manganese concentrations (> 2 mcg/L) may confirm recent acute exposure. Exposures at the OSHA PEL usually do not raise urinary levels above 8 mcg/L. Chelation challenge does not have a role in diagnosis.
3. Hair and nail levels are not useful.

B. Other useful laboratory studies include arterial blood gases or oximetry, chest x-ray (after acute, heavy, symptomatic inhalation exposure), and magnetic resonance imaging (MRI) of the brain.

V. Treatment

A. Emergency and supportive measures

1. **Acute inhalation.** Administer supplemental oxygen. Treat bronchospasm (see p 8) and noncardiogenic pulmonary edema (p 7) if they occur.
2. **Chronic intoxication.** Psychiatric and neurologic effects are treated with the usual psychiatric and antiparkinsonian drugs, but often respond poorly.

B. Specific drugs and antidotes. Calcium EDTA and other chelators have **not** been proved effective after chronic neurologic damage has occurred. The efficacy of chelators early after acute exposure has not been studied.

C. Decontamination (see p 46)

1. **Acute inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
2. **Ingestion.** Because inorganic manganese is so poorly absorbed from the gastrointestinal tract, gut decontamination is probably not necessary. For massive ingestions, particularly of organic compounds (eg, Maneb and MMT), gastric lavage and activated charcoal may be appropriate but have not been studied.

D. Enhanced elimination. There is no known role for dialysis or hemoperfusion.

Barceloux DG: Manganese. *J Toxicol Clin Toxicol* 1999;37(2):293–307. [PMID: 10382563] (Review.)

Ono K et al: Myoclonic involuntary movement associated with chronic manganese poisoning. *J Neurol Sci* 2002;199(1–2):93–96. [PMID: 12084450] (Case report in a 17-year-old welder.)

► MARIJUANA

Neal L. Benowitz, MD

Marijuana consists of the leaves and flowering parts of the plant *Cannabis sativa* and is usually smoked in cigarettes (“joints” or “reefers”) or pipes or added to food (usually cookies or brownies). Resin from the plant may be dried and compressed into blocks called hashish. Marijuana contains a number of cannabinoids; the primary psychoactive one is delta-9-tetrahydrocannabinol (THC). THC is also available in capsule form (dronabinol or Marinol) as an appetite stimulant, used primarily for AIDS-related anorexia, and as treatment for vomiting associated with cancer chemotherapy.

I. Mechanism of toxicity

- A. THC**, which binds to anandamide receptors in the brain, may have stimulant, sedative, or hallucinogenic actions depending on the dose and time after consumption. Both catecholamine release (resulting in tachycardia) and inhibition of sympathetic reflexes (resulting in orthostatic hypotension) may be observed.
- B. Pharmacokinetics.** Only about 10–20% of ingested dronabinol is absorbed, with onset of effects within 30–60 minutes and peak absorption at 2–4 hours. Metabolized by hydroxylation to active and inactive metabolites. Elimination half-life is 20–30 hours, but may be longer in chronic users.

II. Toxic dose. Typical marijuana cigarettes contain 1–3% THC, but more potent varieties may contain up to 15% THC. Hashish contains 3–6% and hashish oil 30–50% THC. Dronabinol is available in 2.5-, 5-, and 10-mg capsules. Toxicity is dose-related, but there is much individual variability, influenced in part by prior experience and degree of tolerance.

III. Clinical presentation

- A. Subjective effects** after smoking a marijuana cigarette include euphoria, palpitations, heightened sensory awareness, and altered time perception followed after about 30 minutes by sedation. More severe intoxication may result in impaired short-term memory, depersonalization, visual hallucinations, and acute paranoid psychosis. Occasionally, even with low doses of THC, subjective effects may precipitate a panic reaction.
- B. Physical findings** may include tachycardia, orthostatic hypotension, conjunctival injection, incoordination, slurred speech, and ataxia. Stupor with pallor, conjunctival injection, fine tremor, and ataxia has been observed in children after they have eaten marijuana cookies.
- C. Other health problems** include salmonellosis and pulmonary aspergillosis from use of contaminated marijuana. Marijuana may be contaminated by paraquat, but the latter is destroyed by pyrolysis and there have been no reports of paraquat toxicity from smoking marijuana.
- D. Intravenous use** of marijuana extract or hash oil may cause dyspnea, abdominal pain, fever, shock, disseminated intravascular coagulation, acute renal failure, and death.

IV. Diagnosis is usually based on the history and typical findings such as tachycardia and conjunctival injection combined with evidence of altered mood or cognitive function.

- A. Specific levels.** Blood levels are not commonly available. Cannabinoid metabolites may be detected in the urine by enzyme immunoassay for up to several days after single acute exposure or weeks after chronic THC exposure. Urine levels do not correlate with degree of intoxication or functional impairment. Hemp and hemp seed products (eg, hemp seed nutrition bars) may provide alternative explanations for positive urine testing. While barely capable of causing a true positive for THC metabolite, they have no pharmacologic effect.

B. Other useful laboratory studies include electrolytes and glucose.

V. Treatment**A. Emergency and supportive measures**

1. Most psychological disturbances may be managed by simple reassurance, possibly with adjunctive use of lorazepam, diazepam, or midazolam (see p 415).
2. Sinus tachycardia usually does not require treatment but if necessary may be controlled with beta blockers.
3. Orthostatic hypotension responds to head-down position and intravenous fluids.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination after ingestion (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Ipecac-induced vomiting may be useful for initial treatment at the scene (eg, children at home) if it can be given within a few minutes of exposure.

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. **Enhanced elimination.** These procedures are not effective owing to the large volume of distribution of cannabinoids.

Sidney S: Cardiovascular consequences of marijuana use. *J Clin Pharmacol* 2002;42(11 Suppl):64–70. [PMID: 12412838] (Marijuana use increases heart rate and blood pressure, and shortens the time to onset of chest pain in patients with angina.)

► MERCURY

Michael J. Kosnett, MD, MPH

Mercury (Hg) is a naturally occurring metal that is mined chiefly as HgS in cinnabar ore. It is converted to three primary forms, each with a distinct toxicology: elemental (metallic) mercury (Hg^0), inorganic mercury salts (eg, mercuric chloride [HgCl_2]), and organic (alkyl and aryl) mercury (eg, methylmercury). Approximately one-third of commercial mercury use is in the manufacture of chlorine and caustic soda; other major uses include electrical equipment, thermometers and other measuring and control instruments, dental amalgam, paints and pigments, and gold mining and extracting. Previous use in pharmaceuticals and biocides has sharply declined, although mercuric chloride is still commonly used as a stool fixative, and some organomercury compounds (such as mercurochrome and thimerosal) are still used as topical antiseptics or preservatives. Some folk medicines contain inorganic mercury compounds, and some Latin American or Caribbean communities have used elemental mercury in religious or cultural rituals. Aquatic organisms can convert inorganic mercury into methylmercury, with resulting bioaccumulation in large carnivorous fish such as swordfish.

- I. **Mechanism of toxicity.** Mercury reacts with sulfhydryl (SH) groups, resulting in enzyme inhibition and pathologic alteration of cellular membranes.
 - A. Elemental and methylmercury are particularly toxic to the CNS. Metallic mercury vapor is also a pulmonary irritant. Methylmercury is associated with neurodevelopmental disorders.
 - B. Inorganic mercuric salts are corrosive to the skin, eyes, and gastrointestinal tract, and are nephrotoxic.
 - C. Inorganic and organic mercury compounds may cause contact dermatitis.
- II. **Toxic dose.** The pattern and severity of toxicity are highly dependent on the form of mercury and the route of exposure, mostly because of different pharmacokinetic profiles. Chronic exposure to any form may result in toxicity. See Table II–34 for a summary of absorption and toxicity.
 - A. **Elemental (metallic) mercury** is a volatile liquid at room temperature.
 1. Hg^0 vapor is rapidly absorbed by the lungs and distributed to the CNS. Airborne exposure to 10 mg/m^3 is considered immediately dangerous to life or health (IDLH), and chemical pneumonitis may occur at levels in excess of 1 mg/m^3 . In occupational settings, overt signs and symptoms of elemental mercury intoxication have generally required months to years of sustained daily exposure to airborne mercury levels of 0.05 to 0.2 mg/m^3 . The recommended workplace limit (ACGIH TLV-TWA) is 0.025 mg/m^3 as an 8-hour time-weighted average; however, some studies suggest that subclinical effects on the CNS and kidneys might occur below this level.
 2. Liquid metallic mercury is poorly absorbed from the gastrointestinal tract, and acute ingestion has been associated with poisoning only in the presence of abnormal gut motility that markedly delays normal fecal elimination, or after peritoneal contamination.
 - B. **Inorganic mercuric salts.** The acute lethal oral dose of mercuric chloride is approximately 1–4 g. Severe toxicity and death have been reported after use

TABLE II-34. SUMMARY OF ABSORPTION AND TOXICITY OF MERCURY COMPOUNDS

Form	Absorption		Toxicity	
	Oral	Inhalation	Neurologic	Renal
Elemental (metallic) mercury				
Hg ⁰ liquid	Poor	NA*	Rare	Rare
Hg ⁰ vapor	NA*	Good	Likely	Possible
Inorganic mercuric salts				
Hg ²⁺	Good	Rare but possible	Rare	Likely
Organic (alkyl) mercury				
RHg ⁺	Good	Rare but possible	Likely	Possible

*NA = Not applicable.

of peritoneal lavage solutions containing mercuric chloride concentrations of 0.2–0.8%.

C. Organic mercury

1. Mercury-containing antiseptics such as mercurochrome have limited skin penetration; however, in rare cases, such as topical application to an infected omphalocele, intoxication has resulted. Oral absorption is significant and may also pose a hazard.
2. Methylmercury is well absorbed after inhalation, ingestion, and probably dermal exposure. Ingestion of 10–60 mg/kg may be lethal, and chronic daily ingestion of 10 mcg/kg may be associated with adverse neurologic and reproductive effects. The US Environmental Protection Agency (EPA) reference dose (RfD), the daily lifetime dose believed to be without potential hazard, is 0.1 mcg/kg/day.
3. Dimethylmercury, a highly toxic synthetic liquid used in analytical chemistry, is well absorbed through the skin, and cutaneous exposure to a few drops has resulted in a delayed but fatal encephalopathy.

III. Clinical presentation

A. Acute inhalation of high concentrations of metallic mercury vapor may cause severe chemical pneumonitis and noncardiogenic pulmonary edema. Acute gingivostomatitis may also occur.

B. Chronic intoxication from inhalation of mercury vapor produces a classic triad of tremor, neuropsychiatric disturbances, and gingivostomatitis.

1. Early stages feature a fine intention tremor of the fingers, but involvement of the face and progression to choreiform movements of the limbs may occur.
2. Neuropsychiatric manifestations include fatigue, insomnia, anorexia, and memory loss. There may be an insidious change in mood to shyness, withdrawal, and depression, combined with explosive irritability and frequent blushing (“erethism”).
3. Subclinical changes in peripheral nerve function and renal function have been reported, but frank neuropathy and nephropathy are rare.
4. Acrodynia, a rare idiosyncratic reaction to chronic mercury exposure, occurs mainly in children and has the following features: pain in the extremities, often accompanied by pinkish discoloration and desquamation (“pink disease”); hypertension; profuse sweating; anorexia, insomnia, irritability, and/or apathy; and a miliarial rash.

C. Acute ingestion of inorganic mercuric salts, particularly mercuric chloride, causes an abrupt onset of hemorrhagic gastroenteritis and abdominal pain. Intestinal necrosis, shock, and death may ensue. Acute oliguric renal failure from acute tubular necrosis may occur within days. Chronic exposure may result in CNS toxicity.

D. Organic mercury compounds, particularly short-chain alkyl compounds such as methylmercury, primarily affect the CNS, causing paresthesias, ataxia, dysarthria, hearing impairment, and progressive constriction of the visual fields. Symptoms first become apparent after several weeks or months.

1. Ethylmercury compounds may also cause gastroenteritis.
2. Phenylmercury compounds produce a pattern of toxicity intermediate between alkyl and inorganic mercury.
3. Methylmercury is a potent reproductive toxin, and perinatal exposure has caused mental retardation and a cerebral palsy-type syndrome in offspring.

IV. Diagnosis depends on integration of characteristic findings with a history of known or potential exposure and presence of elevated mercury blood levels or urinary excretion.

A. Specific levels. Elemental and inorganic mercury follow a biphasic elimination rate (initially rapid, then slow), and both urinary and fecal excretion occur. The urinary elimination half-life is approximately 40 days.

1. **Metallic and inorganic mercury.** Whole-blood, and preferably urine mercury, levels are useful in confirming exposure. In most people without occupational exposure, whole-blood Hg is less than 10 mcg/L and urine Hg is less than 10 mcg/L. Overt neurologic effects have occurred in persons with chronic urine Hg levels greater than 100–200 mcg/L, although lower levels have been reported in some pediatric cases of acrodynia. In patients with acute inorganic mercury poisoning resulting in gastroenteritis and acute tubular necrosis, blood Hg levels are often greater than 500 mcg/L.

2. **Organic mercury.** Methylmercury undergoes biliary excretion and enterohepatic recirculation, with 90% eventually excreted in the feces; as a result, urine levels are not useful. Whole-blood Hg levels greater than 200 mcg/L have been associated with symptoms. The blood mercury half-life is 50–70 days. Hair levels have been used to document remote exposure. Populations eating contaminated fish often have elevated total blood mercury levels. Speciation of inorganic versus organic mercury may be helpful.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver transaminases, urinalysis, chest x-ray, and arterial blood gases (if pneumonitis is suspected). Urinary markers of early nephrotoxicity (microalbuminuria, retinol binding protein, beta-2 microglobulin, and *N*-acetylglucosaminidase) may aid detection of early adverse effects. Formal visual field examination may be useful for organic mercury exposure.

V. Treatment

A. Emergency and supportive measures

1. **Inhalation.** Observe closely for several hours for development of acute pneumonitis and pulmonary edema (see p 7, and give supplemental oxygen if indicated).
2. **Mercuric salt ingestion.** Anticipate severe gastroenteritis and treat shock aggressively with intravenous fluid replacement (see p 16). Vigorous hydration may also help maintain urine output. Acute renal failure is usually reversible, but hemodialysis may be required for 1–2 weeks.
3. **Organic mercury ingestion.** Provide symptomatic supportive care.

B. Specific drugs and antidotes

1. **Metallic (elemental) mercury.** In acute or chronic poisoning, oral **succimer** (DMSA, p 501) or oral **unithiol** (DMPS, p 506) may enhance urinary Hg excretion (although its effect on clinical outcome has not been fully studied). Although **penicillamine** (p 484) is an alternative oral treatment, it may be associated with more side effects and less efficient Hg excretion.
2. **Inorganic mercury salts.** Treatment with intravenous **unithiol** (DMPS, p 506) or intramuscular **BAL** (p 413), if begun within minutes to a few hours after ingestion, may reduce or avert severe renal injury. Because

prompt intervention is necessary, do not delay treatment while waiting for specific laboratory confirmation. Oral **succimer** (DMSA, p 501) is also effective, but its absorption may be limited by gastroenteritis and shock, and it is more appropriately used as a follow-up to DMPS or BAL treatment.

3. **Organic mercury.** In methylmercury intoxication, limited data suggest that oral **succimer** (DMSA, p 501) and oral **N-acetylcysteine** (NAC, p 405) may be effective in decreasing Hg levels in tissues, including the brain.
4. Because BAL may redistribute mercury to the brain from other tissue sites, it should not be used in poisoning by metallic or organic mercury, because the brain is a key target organ.

C. Decontamination (see p 46)

1. Inhalation

- a. Immediately remove the victim from exposure and give supplemental oxygen if needed.
- b. Even minute indoor spills (eg, 1 mL) of metallic mercury can result in hazardous chronic airborne levels. Cover the spill with powdered sulfur, and carefully clean up and discard all residue and contaminated carpeting, porous furniture, and permeable floor covering. Do **not** use a home vacuum cleaner, as this may disperse the liquid mercury, increasing its airborne concentration. For large spills, professional cleanup with self-contained vacuum systems is recommended.

2. **Ingestion of metallic mercury.** In healthy persons, metallic mercury passes through the intestinal tract with minimal absorption, and there is no need for gut decontamination following minor ingestions. With extremely large ingestions, or in patients with abnormally diminished bowel motility or intestinal perforation, there is a risk of chronic intoxication. Multiple-dose cathartics, whole-bowel irrigation (see p 52), or even surgical removal may be necessary, depending on x-ray evidence of mercury retention or elevated blood or urine Hg levels.

3. Ingestion of inorganic mercuric salts

- a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of serious corrosive injury.
- b. **Hospital.** Perform gastric lavage. Administer activated charcoal, although it is of uncertain benefit.
- c. Arrange for endoscopic examination if corrosive injury is suspected.

4. **Ingestion of organic mercury.** After acute ingestion, perform gastric lavage and administer activated charcoal. Immediately stop breast-feeding, but continue to express and discard milk, as some data suggest this may accelerate reduction of blood Hg levels.

D. Enhanced elimination

1. There is no role for dialysis, hemoperfusion, or repeat-dose charcoal in removing metallic or inorganic mercury. However, dialysis may be required for supportive treatment of renal failure, and it may slightly enhance removal of the mercury-chelator complex in patients with renal failure (hemodialysis clearance of the mercury-BAL complex is about 5 mL/min).
2. In patients with chronic methylmercury intoxication, repeated oral administration of an experimental polythiol resin was effective in enhancing Hg elimination by interrupting enterohepatic recirculation.

► METALDEHYDE

Winnie W. Tai, PharmD

Metaldehyde is widely used in the United States as a snail and slug poison. In Europe, it is also used as a solid fuel for small heaters. The pellets are often mistaken for cereal or candy. Common commercial products containing metaldehyde (2–4%) include Cory's Slug and Snail Death, Deadline for Slugs and Snails, and Bug-Geta Snail and Slug Pellets.

I. Mechanism of toxicity

A. The mechanism of toxicity is not well understood. Metaldehyde, like paraldehyde, is a polymer of acetaldehyde, and depolymerization to form acetaldehyde may account for some of its toxic effects. Further metabolism to acetone bodies may contribute to metabolic acidosis.

B. Pharmacokinetics. Readily absorbed with onset of effects in 1–3 hours. Volume of distribution and protein binding are not known. The elimination half-life is approximately 27 hours.

II. Toxic dose. Ingestion of 100–150 mg/kg may cause myoclonus and convulsions, and ingestion of more than 400 mg/kg is potentially lethal. Death occurred in a child after ingestion of 3 g.

III. Clinical presentation. Symptoms usually begin within 1–3 hours after ingestion.

A. Small ingestions (5–10 mg/kg) cause salivation, facial flushing, vomiting, abdominal cramps, diarrhea, and fever.

B. Larger doses may produce irritability, ataxia, drowsiness, myoclonus, opisthotonus, convulsions, and coma. Rhabdomyolysis and hyperthermia may result from seizures or excessive muscle activity. Liver and kidney damage has been reported.

C. Metabolic acidosis and elevated osmolar gap have been reported.

IV. Diagnosis is based on a history of ingestion and clinical presentation. Ask about containers in the garage or planting shed; metaldehyde is frequently packaged in brightly colored cardboard boxes similar to cereal containers.

A. Specific levels. Serum levels are not generally available.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, osmolar gap (may be elevated), and liver enzymes. If rhabdomyolysis is suspected, also perform a urine dipstick for occult blood (myoglobin is positive) and obtain a serum CPK.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).

2. Treat coma (see p 19) and seizures (p 22) if they occur. Paraldehyde should **not** be used to treat seizures because of its chemical similarity to metaldehyde.

3. Treat fluid loss from vomiting or diarrhea with intravenous crystalloid fluids (p 16).

4. Monitor asymptomatic patients for at least 4–6 hours after ingestion.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting, because of the risk of abrupt onset of seizures.

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. There is no apparent benefit from dialysis, hemoperfusion, or forced diuresis. Repeat-dose charcoal has not been studied.

Shintani S et al: Adsorption effects of activated charcoal on metaldehyde toxicity in rats. *Ver Hum Toxicol* 1999;41(1):15–18. [PMID: 9949477] (Activated charcoal was effective in reducing gastrointestinal absorption of metaldehyde in rats.)

► METAL FUME FEVER

Paul D. Blanc, MD, MSPH

Metal fume fever is an acute febrile illness associated with the inhalation of respirable particles of zinc oxide. Although metal fume fever has also been invoked as a generic effect of exposure to numerous metal oxides (copper, cadmium, iron, magnesium, and manganese), there is little evidence to support this. Metal fume fever usually occurs in workplace settings involving welding, melting, or flame-cutting galvanized metal or in brass foundry operations. Zinc chloride exposure may occur from smoke bombs; while it is a severe lung irritant, it does not cause metal fume fever.

- I. **Mechanism of toxicity.** Metal fume fever results from inhalation of zinc oxide (neither ingestion nor parenteral administration induces the illness). The mechanism is uncertain, but may be cytokine-mediated. It does not involve sensitization and can occur with the first exposure.
- II. **Toxic dose.** The toxic dose is variable. Resistance to the condition develops after repeated days of exposure but wears off rapidly when exposure ceases. The ACGIH recommended workplace exposure limit (TLV-TWA) for zinc oxide fumes is 5 mg/m^3 as an 8-hour time-weighted average, which is intended to prevent metal fume fever in most exposed workers. The air level considered immediately dangerous to life or health (IDLH) is 500 mg/m^3 .
- III. **Clinical presentation**
 - A. Symptoms begin 4–8 hours after exposure, when the victim develops fever, malaise, myalgias, and headache. The white blood cell count may be elevated (12,000–16,000). The chest x-ray is usually normal. Typically, all symptoms resolve spontaneously within 24–36 hours.
 - B. Rare asthmatic responses to zinc oxide fumes have been reported but are not part of the metal fume fever syndrome.
 - C. Pulmonary infiltrates and hypoxemia are not consistent with pure metal fume fever and if present suggest possible heavy metal pneumonitis resulting from cadmium or other toxic inhalations (eg, phosgene and nitrogen oxides) associated with metal-working, foundry operations, or welding.
- IV. **Diagnosis.** A history of welding, especially with galvanized metal, and typical symptoms and signs are sufficient to make the diagnosis.
 - A. **Specific levels.** There are no specific tests to diagnose or exclude metal fume fever. Blood or urine zinc determinations do not have a role in clinical diagnosis of the syndrome.
 - B. **Other useful laboratory studies** include CBC, arterial blood gases or oximetry, and chest x-ray (to exclude other disorders).
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. Administer supplemental oxygen, and give bronchodilators if there is wheezing (see pp 7–8). If hypoxemia or wheezing is present, consider other toxic inhalations (see p 213).
 2. Provide symptomatic care (eg, acetaminophen or other antipyretic) as needed; symptoms are self-limited.
 - B. **Specific drugs and antidotes.** There is no specific antidote.
 - C. **Decontamination** is not necessary; by the time symptoms develop, the exposure has usually been over for several hours.
 - D. **Enhanced elimination.** There is no role for these procedures.

Fine JM et al: Characterization of clinical tolerance to inhaled zinc oxide in naive subjects and sheet metal workers. *J Occup Environ Med* 2000;42(11):1085–1091. [PMID: 11094787] (Human experimental study of the metal fume fever response.)

Mechanistic implications for metal fume fever. *J Occup Environ Med* 1998;40(5):454–459. [PMID: 9604183] (In addition to reviewing the mechanism of action of zinc oxide, a detailed reference list addresses in vivo effects.)

► METHANOL

Ilene B. Anderson, PharmD

Methanol (wood alcohol) is a common ingredient in many solvents, windshield-washing solutions, duplicating fluids, and paint removers. It is sometimes used as an ethanol substitute by alcoholics. Although methanol itself produces mainly inebriation, its metabolic products may cause metabolic acidosis, blindness, and death after a characteristic latent period of 6–30 hours.

I. Mechanism of toxicity

A. Methanol is slowly metabolized by alcohol dehydrogenase to formaldehyde and subsequently by aldehyde dehydrogenase to formic acid (formate). Systemic acidosis is caused by both formate and lactate, while blindness is caused primarily by formate. Both ethanol and methanol compete for the enzyme alcohol dehydrogenase, and block the metabolism of methanol to its toxic metabolites.

B. Pharmacokinetics. Methanol is readily absorbed and quickly distributed to the body water ($V_d = 0.6 \text{ L/kg}$). It is not protein bound. It is metabolized slowly by alcohol dehydrogenase via zero-order kinetics, at a rate about one-tenth that of ethanol. The reported “half-life” ranges from 2 to 24 hours, depending on whether metabolism is blocked (eg, by ethanol or fomepizole). Only about 3% is excreted unchanged by the kidneys and less than 10–20% through the breath.

II. Toxic dose. The fatal oral dose of methanol is estimated to be 30–240 mL (20–150 g). The minimum toxic dose is approximately 100 mg/kg. Elevated serum methanol levels have been reported after extensive dermal exposure and concentrated inhalation. The ACGIH recommended workplace exposure limit (TLV-TWA) for inhalation is 200 ppm as an 8-hour time-weighted average, and the level considered immediately dangerous to life or health (IDLH) is 6000 ppm.

III. Clinical presentation

A. In the first few hours after ingestion, methanol-intoxicated patients present with inebriation and gastritis. Acidosis is not usually present because metabolism to toxic products has not yet occurred. There may be a noticeable elevation in the osmolar gap (see p 32); an osmolar gap of as little as 10 mOsm/L is consistent with toxic concentrations of methanol.

B. After a latent period of up to 30 hours, severe anion gap metabolic acidosis, visual disturbances, blindness, seizures, coma, and death may occur. Patients describe the visual disturbance as haziness or “like standing in a snowfield.” Fundoscopic examination may reveal optic disc hyperemia, venous engorgement, or papilledema. The latent period is longer when ethanol has been ingested concurrently with methanol.

IV. Diagnosis is usually based on the history, symptoms, and laboratory findings because stat methanol levels are rarely available. Calculation of the osmolar and anion gaps (see p 33) can be used to estimate the methanol level and to predict the severity of the ingestion. A large anion gap not accounted for by elevated lactate suggests possible methanol (or ethylene glycol) poisoning, because the anion gap in these cases is mostly nonlactate.

A. Specific levels

1. **Serum methanol** levels higher than 20 mg/dL should be considered toxic, and levels higher than 40 mg/dL should be considered very serious. After the latent period, a low or nondetectable methanol level does not rule out serious intoxication in a symptomatic patient because all the methanol may already have been metabolized to formate.

2. Elevated **serum formate** concentrations may confirm the diagnosis and are a better measure of toxicity, but formate levels are not yet widely available.

B. Other useful laboratory studies include electrolytes (and anion gap), glucose, BUN, creatinine, serum osmolality and osmolar gap, arterial blood gases, ethanol level, and lactate level.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19) and seizures (p 22) if they occur.
3. Treat metabolic acidosis with intravenous sodium bicarbonate (see p 419). Correction of acidosis should be guided by arterial blood gases.

B. Specific drugs and antidotes

1. Administer **fomepizole** (see p 448) or **ethanol** (p 444) to saturate the enzyme alcohol dehydrogenase and prevent the formation of methanol's toxic metabolites. Therapy is indicated in patients with the following:
 - a. A history of significant methanol ingestion, when methanol serum levels are not immediately available and the osmolar gap is greater than 10 mOsm/L.
 - b. Metabolic acidosis and an osmolar gap greater than 10 mOsm/L not accounted for by ethanol.
 - c. A methanol blood concentration greater than 20 mg/dL.
2. **Folic or folinic acid** (see p 447) may enhance the conversion of formate to carbon dioxide and water. A suggested dose of folic acid is 50 mg IV every 4 hours.

C. Decontamination (see p 46)

1. **Prehospital.** Do **not** induce vomiting or administer charcoal.
2. **Hospital.** Aspirate gastric contents if this can be performed within 30–60 minutes of ingestion. Activated charcoal is not likely to be useful because the effective dose is very large and methanol is rapidly absorbed from the GI tract.

D. Enhanced elimination.

Hemodialysis rapidly removes both methanol (half-life reduced to 3–6 hours) and formate. The indications for dialysis are suspected methanol poisoning with significant metabolic acidosis, visual abnormalities, an osmolar gap greater than 10 mOsm/L, or a measured serum methanol concentration greater than 50 mg/dL. Dialysis should be continued until the methanol concentration is less than 20 mg/dL.

Barceloux DG et al: American Academy of Clinical Toxicology practice guidelines on the treatment of methanol poisoning. *J Toxicol Clin Toxicol* 2002;40(4):415–446. [PMID: 12216995] (Review of clinical presentation and consensus guidelines on management of methanol poisoning.)

Kerns W 2nd et al: Formate kinetics in methanol poisoning. *J Toxicol Clin Toxicol* 2002;40(2):137–143. [PMID: 12126185] (Eight methanol-poisoned patients had an average endogenous elimination half-life of the formate metabolite of 205 minutes, compared to 150 minutes during dialysis. The overall formate CL during dialysis was 223 mL/min.)

► METHEMOGLOBINEMIA

Paul D. Blanc, MD, MSPH

Methemoglobin is an oxidized form of hemoglobin. Many oxidant chemicals and drugs are capable of inducing methemoglobinemia: nitrites and nitrates, bromates and chlorates, aniline derivatives, antimalarial agents, dapsone, propanil (an herbicide), sulfonamides, local anesthetics, and numerous others (Table II–35). Occupational risk groups include chemical and munitions workers. An important environmental source for methemoglobinemia in infants is nitrate-contaminated well water. Amyl and butyl nitrite are abused for their alleged sexual enhancement properties. Oxides of nitrogen and other oxidant combustion products make smoke inhalation an important potential cause of methemoglobinemia.

I. Mechanism of toxicity

- A. Methemoglobin inducers act by oxidizing ferrous (Fe^{2+}) to ferric (Fe^{3+}) hemoglobin. This abnormal hemoglobin is incapable of carrying oxygen, inducing a

TABLE II–35. SELECTED AGENTS CAPABLE OF INDUCING METHEMOGLOBINEMIA

Local anesthetics Benzocaine Cetacaine Lidocaine Prilocaine	Analgesics Phenazopyridine Phenacetin Nitrites and nitrates Ammonium nitrate Amyl nitrite Butyl nitrite Isobutyl nitrite Sodium nitrate	Miscellaneous Aminophenol Aniline dyes Bromates Chlorates Metoclopramide Nitrobenzene Nitroethane Nitrogen oxides Nitroglycerin Propanil Sodium nitrite
--	---	---

functional anemia. In addition, the shape of the oxygen-hemoglobin dissociation curve is altered, aggravating cellular hypoxia.

- B.** Methemoglobinemia does not directly cause hemolysis; however, many oxidizing agents that induce methemoglobinemia may also cause hemolysis through either hemoglobin (Heinz body) or cell membrane effects, particularly in patients with low tolerance for oxidative stress (eg, those with glucose-6-phosphate dehydrogenase [G6PD] deficiency).
- II. Toxic dose.** The ingested dose or inhaled air level of toxin required to induce methemoglobinemia is highly variable. Neonates and persons with congenital methemoglobin reductase deficiency or G6PD deficiency have an impaired ability to regenerate normal hemoglobin and are therefore more likely to accumulate methemoglobin after oxidant exposure. Concomitant hemolysis suggests either heavy oxidant exposure or increased cell vulnerability.
- III. Clinical presentation.** The severity of symptoms usually correlates with measured methemoglobin levels (Table II–36).
- A.** Symptoms and signs are caused by decreased blood oxygen content and cellular hypoxia and include headache, dizziness, and nausea, progressing to dyspnea, confusion, seizures, and coma. Even at low levels, skin discoloration (“chocolate cyanosis”), especially of the nails, lips, and ears, is striking.
- B.** Usually, mild methemoglobinemia (less than 15–20%) is well tolerated and will resolve spontaneously. Continued metabolism of oxidant compounds from a long-acting parent compound (eg, dapsone) may lead to prolonged effects (2–3 days).
- IV. Diagnosis.** The patient with mild to moderate methemoglobinemia appears markedly cyanotic, yet may be relatively asymptomatic. The arterial oxygen partial pressure (pO₂) is normal. The diagnosis is suggested by the finding of “chocolate brown” blood (dry a drop of blood on filter paper and compare with normal blood), which is usually apparent when the methemoglobin level exceeds

TABLE II–36. CORRELATION OF SYMPTOMS WITH METHEMOGLOBIN LEVELS

Methemoglobin Level ^a	Typical Symptoms
< 15%	Usually asymptomatic
15–20%	Cyanosis, mild symptoms
20–45%	Marked cyanosis, moderate symptoms
45–70%	Severe cyanosis, severe symptoms
> 70%	Usually lethal

^aThese percentages assume normal range total hemoglobin concentrations. Concomitant anemia may lead to more severe symptoms at lower proportional methemoglobinemia.

15%. Differential diagnosis includes other causes of cellular hypoxia (eg, carbon monoxide, cyanide, and hydrogen sulfide) and sulfhemoglobinemia.

A. Specific levels. The co-oximeter type of arterial blood gas analyzer will directly measure oxygen saturation and methemoglobin percentages (measure as soon as possible, because levels fall rapidly in vitro).

1. **Note:** Sulfhemoglobin and the antidote methylene blue both produce erroneously high levels on the co-oximeter: a dose of 2 mL/kg methylene blue gives a false-positive methemoglobin of approximately 15%.
2. The routine arterial blood gas machine measures the serum pO_2 (which is normal) and calculates a falsely normal oxygen saturation.
3. Pulse oximetry is **not** reliable; it does not accurately reflect the degree of hypoxemia in a patient with severe methemoglobinemia, and may appear falsely abnormal in a patient who has been given methylene blue.

B. Other useful laboratory studies include electrolytes and glucose. If hemolysis is suspected, add CBC, haptoglobin, peripheral smear, and urinalysis dipstick for occult blood (free hemoglobin is positive).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Usually, mild methemoglobinemia (<15–20%) will resolve spontaneously and requires no intervention.

B. Specific drugs and antidotes

1. **Methylene blue** (see p 466) is indicated in the symptomatic patient with methemoglobin levels higher than 20% or when even minimal compromise of oxygen-carrying capacity is potentially harmful (eg, preexisting anemia, congestive heart failure, pneumocystis pneumonia, angina pectoris, etc). Give methylene blue, 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution), over several minutes. **Caution:** Methylene blue can slightly worsen methemoglobinemia when given in excessive amounts; in patients with G6PD deficiency, it may aggravate methemoglobinemia and cause hemolysis.
2. **Ascorbic acid**, which can reverse methemoglobin by an alternate metabolic pathway, is of minimal use acutely because of its slow action.

C. Decontamination (see p 46) depends on the specific agent involved.

D. Enhanced elimination (see p 54)

1. If methylene blue is contraindicated (eg, G6PD deficiency) or has not been effective, **exchange transfusion** may rarely be necessary in patients with severe methemoglobinemia.
2. **Hyperbaric oxygen** is theoretically capable of supplying sufficient oxygen independent of hemoglobin, and may be useful in extremely serious cases that do not respond rapidly to antidotal treatment.

Methemoglobinemia following unintentional ingestion of sodium nitrite—New York, 2002. *MMWR* 2002 Jul 26;51(29):639–642. [PMID: 12186221] (Five members of a family were poisoned after eating a meal seasoned with this white crystalline substance from a plastic bag labeled “iodized table salt.”)

Wright RO et al: Methemoglobinemia: etiology, pharmacology, and clinical management. *Ann Emerg Med* 1999;34(5):646–656. [PMID: 10533013] (Excellent review including causal agents and treatment.)

► METHYL BROMIDE

Delia A. Dempsey, MS, MD

Methyl bromide is an odorless, colorless extremely toxic gas used as a fumigant on soil, perishable foods, and in buildings. It is a potent alkylating agent and is used in the chemical industry. For its use as a fumigant, fields or buildings are evacuated and covered with a giant tarp, and the gas is introduced. After 12–24 hours, the tarp

is removed, and the area is ventilated and then tested for residual methyl bromide before reoccupation. In 2005, most use of methyl bromide will be phased out in developed countries.

I. Mechanism of toxicity

A. Methyl bromide is a potent nonspecific alkylating agent with a special affinity for sulfhydryl and amino groups. Limited data indicate that toxicity is either the result of direct alkylation of cellular components (eg, glutathione, proteins, or DNA) or formation of toxic metabolites from methylated glutathione. Animal data clearly indicate that its toxicity does not result from the bromide ion.

B. Pharmacokinetics. Inhaled methyl bromide is rapidly distributed to all tissues and metabolized. In sublethal animal studies, approximately 50% is eliminated as exhaled carbon dioxide, 25% is excreted in urine and feces, and 25% is bound to tissues as a methyl group. The elimination half-life of the bromide ion is 9–15 days.

II. Toxic dose. Methyl bromide is threefold heavier than air and may accumulate in low-lying areas, and it may seep via piping or conduits from fumigated buildings into adjacent structures. It may condense to a liquid at cold temperatures (38.5°F or 3.6°C) and then vaporize when temperatures rise. Methyl bromide gas lacks warning properties, so the lacrimator chloropicrin (2%) is usually added. However, chloropicrin has a different vapor pressure and may dissipate at a different rate, limiting its warning properties.

A. Inhalation is the most important route of exposure. The ACGIH recommended workplace exposure limit (TLV-TWA) in air is 1 ppm (3.9 mg/m³) as an 8-hour time-weighted average. Toxic effects are generally seen at levels of 200 ppm, and the air level considered immediately dangerous to life or health (IDLH) is 250 ppm. NIOSH considers methyl bromide a potential occupational carcinogen.

B. Skin irritation and absorption may occur, causing burns and systemic toxicity. Methyl bromide may penetrate clothing and some protective gear. Retention of the gas in clothing and rubber boots can be a source of prolonged dermal exposure.

III. Clinical presentation

A. Acute irritant effects on the eyes, mucous membranes, and upper respiratory tract are attributed to the added lacrimator chloropicrin. (Lethal exposures can occur without warning if chloropicrin has not been added.) Moderate skin exposure can result in dermatitis and, in severe cases, chemical burns.

B. Acute systemic effects are usually delayed several hours and may include malaise, visual disturbances, headache, nausea, vomiting, tremor, seizures, and coma. In some cases there is a 6- to 48-hour prodrome of nausea, vomiting, and other symptoms before the onset of intractable seizures and coma. Death may be caused by fulminant respiratory failure with noncardiogenic pulmonary edema or complications of status epilepticus. Sublethal exposure may result in flu-like symptoms, respiratory complaints, or chronic effects.

C. Chronic neurologic sequelae can result from chronic exposure or a sublethal acute exposure. A wide spectrum of neurologic and psychiatric problems may occur that may be reversible (months to years) or irreversible. These include agitation, delirium, dementia, psychoneurotic symptoms, psychosis, visual disturbances, vertigo, aphasia, ataxia, peripheral neuropathies, myoclonic jerking, tremors, and seizures.

IV. Diagnosis is based on a history of exposure to the compound and on clinical presentation.

A. Specific levels. Bromide levels in patients with acute methyl bromide exposure are usually well below the toxic range for bromism and may be only mildly elevated compared to unexposed (see Bromides, p 140). Nontoxic bromide levels do not rule out methyl bromide poisoning. Levels of methylated proteins or DNA are being investigated as possible biomarkers for methyl bromide exposure.

B. Other useful laboratory studies include electrolytes, glucose, BUN, and creatinine. If there is respiratory distress, also perform arterial blood gases or oximetry and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Administer supplemental oxygen, and treat bronchospasm (see p 8), pulmonary edema (p 7), seizures (p 22), and coma (p 19) if they occur. Intractable seizures usually predict a fatal outcome. Consider induction of barbiturate coma with a short-acting agent such as pentobarbital (p 485); and consult a neurologist as soon as possible.
2. Monitor patients for a minimum of 6–12 hours to detect development of delayed symptoms, including seizures and noncardiogenic pulmonary edema.

B. Specific drugs and antidotes. Theoretically, *N*-acetylcysteine (NAC, p 405) or dimercaprol (BAL, p 413) can offer a reactive sulfhydryl group to bind free methyl bromide, although neither agent has been critically tested. Some data suggest that toxicity may be due to toxic metabolites formed from methylated glutathione; if this is true then NAC could possibly exacerbate toxicity. Neither agent can be recommended at this time.

C. Decontamination (see p 46). Properly trained personnel should use self-contained breathing apparatus and chemical-protective clothing before entering contaminated areas. The absence of irritant effects from chloropicrin does not guarantee that it is safe to enter without protection.

1. Remove victims from exposure and administer supplemental oxygen if available.
2. If exposure is to liquid methyl bromide, remove contaminated clothing and wash affected skin with soap and water. Irrigate exposed eyes with copious water or saline.

D. Enhanced elimination. There is no role for these procedures.

Horowitz BZ et al: An unusual exposure to methyl bromide leading to fatality. *J Toxicol Clin Toxicol* 1998;36(4):353–357. [PMID: 9711202] (Exposure was caused by seepage of the gas from a fumigated home to an adjacent guest house via underground conduits. Serum Br was 27 mg/dL and postmortem levels of MeBr were found in the blood, liver, and adipose tissue.)

► METHYLENE CHLORIDE

Binh T. Ly, MD

Methylene chloride (dichloromethane, DCM) is a volatile, colorless liquid with a chloroform-like odor. It has a wide variety of industrial uses, many of which are based on its solvent properties, including paint stripping, pharmaceutical manufacturing, metal cleaning and degreasing, film base production, agricultural fumigation, and plastics manufacturing. It is not known to occur naturally. Methylene chloride is metabolized to carbon monoxide *in vivo* and may produce phosgene, chlorine, or hydrogen chloride upon combustion.

I. Mechanism of toxicity

- A. Solvent effects.** Similar to other hydrocarbons, DCM is an irritant to mucous membranes, defats the skin epithelium, and may sensitize the myocardium to arrhythmogenic effects of catecholamines.
- B. Anesthetic effects.** Like other halogenated hydrocarbons, DCM can cause CNS depression and general anesthesia.
- C. Carbon monoxide (CO)** is generated *in vivo* during metabolism by the mixed-function oxidases (P-450 2E1) in the liver. Elevated carboxyhemoglobin levels may be delayed and prolonged, with COHgb levels as high as 50% reported. (See also Carbon Monoxide, p 151.)

D. Methylene chloride is a **suspected human carcinogen** (IARC 2B, see p 527).

II. Toxic dose. Toxicity may occur after inhalation or ingestion.

A. Inhalation. OSHA has recently reduced their permissible exposure limit (PEL) from 500 ppm to 25 ppm as an 8-hour time-weighted average. The ACGIH workplace threshold limit value (TLV-TWA) is 50 ppm (174 mg/m³) for an 8-hour shift, which may result in a carboxyhemoglobin level of 3–4%. The air level considered immediately dangerous to life or health (IDLH) is 2300 ppm. The odor threshold is about 100–200 ppm.

B. Ingestion. The acute oral toxic dose is approximately 0.5–5 mL/kg.

III. Clinical presentation

A. Inhalation is the most common route of exposure and may cause mucous membrane and skin irritation, nausea, vomiting, and headache. Ocular exposure can cause conjunctival irritation. Severe exposure may lead to pulmonary edema or hemorrhage, cardiac arrhythmias, and CNS depression with respiratory arrest.

B. Ingestion can cause corrosive injury to the gastrointestinal tract and systemic intoxication. Renal and hepatic injury and pancreatitis have been reported.

C. Dermal exposure can cause dermatitis or chemical burns, and systemic symptoms can result from skin absorption.

D. Chronic exposure can cause bone marrow, hepatic, and renal toxicity. Methylene chloride is a known animal and suspected human carcinogen (IARC 2B).

IV. Diagnosis is based on a history of exposure and clinical presentation.

A. Specific levels

1. **Carboxyhemoglobin** levels should be obtained serially as peak COHgb levels may be delayed.

2. Expired air and blood or urine levels of **methylene chloride** may be obtained to assess workplace exposure but are not useful in clinical management.

B. Other useful laboratory studies include CBC, electrolytes, glucose, BUN, creatinine, liver transaminases, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).

2. Administer supplemental oxygen, and treat coma (see p 19) and pulmonary edema (p 7) if they occur.

3. Monitor the ECG for at least 4–6 hours, and treat arrhythmias (pp 10–15) if they occur. Avoid the use of catecholamines (eg, epinephrine, dopamine), which may precipitate cardiac arrhythmias. Tachyarrhythmias caused by myocardial sensitization may be treated with **esmolol** (see p 443), 0.025–0.1 mg/kg/min IV, or **propranolol** (p 496), 1–2 mg IV.

4. If corrosive injury is suspected after ingestion, consult a gastroenterologist regarding possible endoscopy.

B. Specific drugs and antidotes. Administer 100% **oxygen** by tight-fitting mask or endotracheal tube if the carboxyhemoglobin level is elevated. Consider hyperbaric oxygen (HBO) if the COHgb level is markedly elevated and the patient has marked CNS depression.

C. Decontamination (see p 46)

1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen, if available.

2. **Skin and eyes.** Remove contaminated clothing, and wash exposed skin with soap and water. Irrigate exposed eyes with copious saline or water.

3. **Ingestion** (see p 48)

a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of rapid CNS depression.

b. **Hospital.** Perform nasogastric suction (if there has been a large, recent ingestion), and administer activated charcoal. The effectiveness of charcoal is not known.

- D. Enhanced elimination.** There is no documented efficacy for repeat-dose activated charcoal, hemodialysis, or hemoperfusion. While treatment with hyperbaric oxygen (HBO) may enhance elimination of DCM, its efficacy for patients with acute poisoning remains unproven.

Chang YL et al: Diverse manifestations of oral methylene chloride poisoning: report of 6 cases. *J Toxicol Clin Toxicol* 1999;37(4):497–504. [PMID: 10465248] (Six patients with oral DCM poisoning. CNS depression and corrosive GI injury were the most common findings; renal and hepatic failure and acute pancreatitis also occurred. COHgb was measured in only two patients and levels were 8.4% and 35%.)

Raphael M et al: Acute methylene chloride intoxication—a case report on domestic poisoning. *Eur J Emerg Med* 2002;9(1):57–59. [PMID: 11989499] (Unusual case of DCM poisoning with COHgb level of 30% due to use of an aerosol spray in the home.)

► MOLDS

John R. Balmes, MD

Fungi are ubiquitous in all environments and play a critical ecological role by decomposing organic matter. “Mold” is the common term for multicellular fungi that grow as a mat of intertwined microscopic filaments (hyphae). Molds are pervasive in the outdoor environment, but may also be present indoors under certain conditions, primarily in the presence of excessive moisture from leaks in roofs or walls, plant pots, or pet urine. The most common indoor molds are *Cladosporium*, *Penicillium*, *Aspergillus*, and *Alternaria*. Other molds that can grow indoors include *Fusarium*, *Trichoderma*, and *Stachybotrys*; the presence of these molds often indicates a long-standing problem with water leakage or damage.

- I. Mechanism of toxicity.** Molds and other fungi may adversely affect human health through three processes: allergy, infection, and toxicity.

A. Allergy. Outdoor molds are generally more abundant and important in allergic disease than indoor molds. The most important indoor allergenic molds are *Penicillium* and *Aspergillus* species. Outdoor molds, such as *Cladosporium* and *Alternaria*, can often be found at high levels indoors if there is abundant access for outdoor air (eg, open windows). Homes and buildings that have excessive moisture or water damage can lead to enhanced growth of allergenic fungi.

B. Infection. Several fungi cause superficial infections involving the skin or nails. A very limited number of pathogenic fungi (eg, *Blastomyces*, *Coccidioides*, *Cryptococcus*, and *Histoplasma*) can infect nonimmunocompromised individuals. In contrast, persons with severe immune dysfunction (eg, cancer patients on chemotherapy, organ transplant patients on immunosuppressive drugs, patients with HIV infection) are at significant risk for more severe opportunistic fungal infection (eg, *Candida* and *Aspergillus*).

C. Mycotoxins and glucans. Some species of fungi are capable of producing mycotoxins, while most molds have one of a group of substances known as glucans in their cell walls. Serious veterinary and human mycotoxicoses have been documented following ingestion of foods heavily overgrown with toxigenic mold species. Inhalational exposure to high concentrations of mixed organic dusts (often in occupational settings) is associated with **organic dust toxic syndrome** (ODTS), an acute febrile illness. This self-limited condition is generally attributed to bacterial endotoxins and potentially to mold glucans, rather than to mycotoxins. Currently there is insufficient evidence to confirm that indoor environmental exposures to mycotoxins from toxigenic mold species results in disease. In 1994 the CDC reported that a cluster of cases of acute idiopathic pulmonary hemorrhage (AIPH) in infants from Cleveland was associated with home contamination by *Stachybotrys chartarum*. However, a subsequent detailed reevaluation of the original data led the CDC to

conclude that there was insufficient evidence to causally link the Cleveland cluster of AIPH to *S chartarum* exposure.

D. Volatile organic compounds (VOCs), including low-molecular-weight alcohols, aldehydes, and ketones, are generated by molds, and are often responsible for the musty, disagreeable odor associated with indoor molds. A role for these VOCs in some building-related symptoms is possible.

II. Toxic dose. Because mycotoxins are not volatile, exposure would require inhalation of aerosolized spores, mycelial fragments, or contaminated substrates. The toxic inhaled dose of mycotoxin for humans is not known. Based on experimental data from single-dose in vivo studies, *Stachybotrys chartarum* spores (intranasally in mice or intratracheally in rats) high doses (more than 30 million spores/kg) can produce pulmonary inflammation and hemorrhage. The no-effect dose in rats (3 million spores/kg) corresponds to a continuous 24-hour exposure to 2.1 million spores/m³ for infants, 6.6 million spores/m³ for a school-age child, or 15.3 million spores/m³ for an adult. These spore concentrations are much higher than those measured in building surveys.

III. Clinical presentation

A. Mold allergy occurs in atopic individuals who develop IgE antibodies to a wide range of indoor and outdoor allergens, including animal dander, dust mites, and weed, tree, and grass pollens. Allergic responses are most commonly experienced as asthma or allergic rhinitis ("hay fever"). A much less common, but more serious immunological condition, **hypersensitivity pneumonitis (HP)**, may follow exposure (often occupational) to relatively high concentrations of fungal (and other microbial) proteins.

B. Infection due to pathogenic fungi is generally unrelated to exposure to molds from identifiable point sources and is beyond the scope of this chapter.

C. Organic dust toxic syndrome presents as a flu-like illness with an onset 4 to 8 hours after a heavy exposure (such as shoveling compost). Symptoms resolve without treatment over 24 hours.

D. "Sick building syndrome," or "non specific building-related illness," represents a poorly defined set of symptoms that are attributed to a building's indoor environment, and can include neurologic, gastrointestinal, dermatologic, and respiratory complaints. The potential role of building-associated exposure to molds in some of these cases is suspected, but the mechanism is not clear. Existing data do not support a specific role for mycotoxins in this syndrome.

IV. Diagnosis. A history of recurrent respiratory symptoms associated with a specific building environment is consistent with either asthma or HP. Inquire about home, school, or work building conditions. If the conditions suggest the likelihood of mold contamination, consult with a specialist trained in the evaluation of building environments (eg, an industrial hygienist or a structural engineer). Mold risk is increased with a history of prior water damage or leak even if not ongoing, especially in the context of damaged drywall or carpeting on concrete.

A. Specific tests. Allergen skin prick testing or radioallergosorbent (RAST) testing can confirm the presence of specific IgE-mediated allergy to common fungi. Testing for the presence of IgG precipitating antibodies can confirm exposure to HP-inducing fungi, but a positive test does not confirm the diagnosis of HP. There are no specific blood or urine tests for mycotoxin exposure.

B. Other useful laboratory studies. Pulmonary function testing is helpful in distinguishing asthma (obstructive pattern with a normal diffusing capacity) from HP (restrictive pattern with a low diffusing capacity). Chest x-ray or high-resolution chest CT scanning may suggest the presence of interstitial lung disease consistent with HP or active or past fungal infection. Histological examination of lung tissue obtained from transbronchial or open lung biopsy may be necessary to confirm the diagnosis of HP.

C. Environmental evaluation. Indoor air samples with contemporaneous outdoor air samples can assist in evaluating whether or not there is mold growth indoors; air samples may also assist in evaluating the extent of potential indoor exposure. Bulk, wipe, and wall cavity samples may indicate the pres-

ence of mold, but do not adequately characterize inhalational exposures of building occupants.

V. Treatment

A. Emergency and supportive measures. Treat bronchospasm (see p 8) and hypoxemia (p 7) if they are present.

B. Specific drugs and antidotes. None.

C. Decontamination of the environment (remediation). Mold overgrowth in indoor environments should be remediated, not only because it may produce offensive odors and adverse health effects, but because it physically destroys the building materials on which it grows. A patient with HP due to sensitization to a specific fungus present in a building environment is not likely to improve until excess exposure is eliminated. Once the source of moisture that supports mold growth has been eliminated, active mold growth can be halted. Colonized porous materials such as clothing or upholstery can be cleaned using washing or dry cleaning as appropriate, and need not be discarded unless cleaning fails to restore an acceptable appearance and odor. Carpeting, drywall, and other structural materials, once contaminated, may present a greater remediation challenge.

D. Enhanced elimination. Not relevant.

[PMID: 11916692] (The largest study to date of airborne indoor and outdoor fungi. *Cladosporium*, *Penicillium*, nonsporulating fungi, and *Aspergillus* were the most commonly identified species. *Stachybotrys chartarum* was identified in the indoor air in 6% of the buildings and in the outdoor air of 1% of the buildings.)

► MONOAMINE OXIDASE INHIBITORS

Neal L. Benowitz, MD

Most monoamine oxidase (MAO) inhibitors are used in treating severe depression; **procarbazine** is a cancer chemotherapeutic drug. Available drugs in this class include **furazolidone** (Furoxone™), **isocarboxazid** (Marplan™), **pargyline** (Eutonyl™), **phenelzine** (Nardil™), **procarbazine** (Matulane™), and **tranylcypromine** (Parnate™). **Moclobemide** (Aurorix™) is available in many countries but not in the United States. Serious toxicity from MAO inhibitors occurs either with overdose or owing to interactions with certain other drugs or foods (Table II–37). **Selegiline** (El-depryl), a MAO type B inhibitor, is not generally associated with the same toxicity or drug interactions with the other MAO inhibitors (which act on MAO type A), although there have been reports of adverse interactions with meperidine. The popular herbal product for depression, **St. John's Wort** (*Hypericum perforatum*), appears to act in part as a monoamine oxidase inhibitor.

I. Mechanism of toxicity. MAO inhibitors irreversibly inactivate MAO, an enzyme responsible for degradation of catecholamines within neurons in the CNS. MAO is also found in the liver and the intestinal wall, where it metabolizes tyramine and therefore limits its entry into the systemic circulation. Moclobemide is a reversible MAO inhibitor and is less hazardous than the other agents.

A. Toxicity results from release of excessive neuronal stores of vasoactive amines, inhibition of metabolism of catecholamines or interacting drugs, or absorption of large amounts of dietary tyramine (which in turn releases catecholamines from neurons).

TABLE II-37. INTERACTIONS WITH MONOAMINE OXIDASE INHIBITORS^a

Drugs		Foods
Amphetamines	Metaraminol	Beer
Buspirone	Methyldopa	Broad bean pods and Fava beans
Clomipramine	Methylphenidate	Cheese (natural or aged)
Cocaine	Paroxetine	Chicken liver
Dextromethorphan	Phenylephrine	Pickled herring
Ephedrine	Phenylpropanolamine	Smoked, pickled, or aged meats
Fluoxetine	Reserpine	Snails
Fluoxetine	Sertraline	Spoiled or bacterially contaminated foods
Guanethidine	Tramadol	Summer sausage
L-Dopa	Trazodone	Wine (red)
LSD (lysergic acid diethylamide)	Tryptophan	Yeast (dietary supplement and Marmite)
MDMA	Venlafaxine	
Meperidine (Demerol)		

^aPossible interactions, based on case reports or pharmacologic considerations.

- B.** In addition, severe rigidity and hyperthermia may occur when patients receiving MAO inhibitors use therapeutic doses of meperidine (Demerol), dextromethorphan, fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), venlafaxine (Effexor), or tryptophan; the mechanism is unknown but may be related to inhibition of serotonin metabolism in the CNS, resulting in "serotonin syndrome" (see p 22).
- II. Toxic dose.** MAO inhibitors have a low therapeutic index. Acute ingestion of 2–3 mg/kg or more should be considered potentially life threatening. Serious drug or food interactions may occur in patients receiving therapeutic doses of MAO inhibitors. **Note:** Because of irreversible MAO inhibition, adverse drug interactions may occur for up to 2 weeks after discontinuing MAO inhibitors. Interactions may also occur when MAO inhibitors are started within 10 days of stopping fluoxetine, owing to the long half-life of fluoxetine.
- III. Clinical presentation.** Symptoms may be delayed 6–24 hours after acute overdose, but occur rapidly after ingestion of interacting drugs or foods in a patient on chronic MAO inhibitor therapy. Because of irreversible inactivation of MAO, toxic effects (and the potential for drug or food interactions) may persist for several days.
- A.** Anxiety, restlessness, flushing, headache, tremor, myoclonus, hyperreflexia, sweating, shivering, tachypnea, tachycardia, and moderate hypertension are common with mild intoxication.
- B.** Severe intoxication may result in severe hypertension (which may be complicated by intracranial hemorrhage), delirium, hyperthermia, and eventually cardiovascular collapse and multisystem failure.
- C.** Hypotension, particularly when upright (orthostatic hypotension), is seen with therapeutic dosing and also may occur with overdose.
- IV. Diagnosis** is based on clinical features of sympathomimetic drug intoxication with a history of MAO inhibitor use, particularly with use of drugs or foods known to interact. Serotonin syndrome (see p 22) is suspected when the patient has myoclonic jerking, hyperreflexia, diaphoresis, and hyperthermia.
- A. Specific levels.** Specific drug levels are not available. Most agents are not detectable on comprehensive urine toxicology screening.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, CPK, 12-lead ECG, and ECG monitoring. If intracranial hemorrhage is suspected, perform a CT head scan.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.

2. Treat hypertension (see p 17), hypotension (p 16), coma (p 19), seizures (p 22), and hyperthermia (p 21) if they occur.
3. Continuously monitor temperature, other vital signs, and ECG for a minimum of 6 hours in asymptomatic patients, and admit all symptomatic patients for continuous monitoring for 24 hours.

B. Specific drugs and antidotes

1. Since the hypertension is catecholamine-mediated, alpha-adrenergic blockers (eg, phentolamine, p 487) or combined alpha- and beta-adrenergic blockers (eg, labetalol, p 459) are particularly useful.
2. **Serotonin syndrome** should be treated with sedation and cooling. Anecdotal reports suggest possible benefit with **cyproheptadine** (Periactin), 4 mg PO every hour for 3 doses (see p 430), or **methysergide** (Sansert), 2 mg PO every 6 hours for 3 doses, presumably because of their serotonin-antagonist activity.

C. Decontamination (see p 46)

1. **Prehospital.** Administer activated charcoal if available. Ipecac-induced vomiting may be useful for initial treatment at the scene (eg, children at home) if it can be given within a few minutes of an acute overdose. However, it should not be used for patients with suspected food or drug interaction because of the risk of aggravating hypertension.
2. **Hospital.** Administer activated charcoal. Perform gastric lavage for a suspected large overdose.

D. Enhanced elimination. Dialysis and hemoperfusion are not effective. Repeat-dose activated charcoal has not been studied.

FitzSimmons CR, Metha S: Serotonin syndrome caused by overdose with paroxetine and moclobemide. *J Accid Emerg Med* 1999;16(4):293–295. [PMID: 10417944] (Case report.)

Prueter C et al: Ping-pong gaze in combined intoxication with tranylcypromine, thioridazine, and clomipramine. *Neuropsychiatry Neuropsychol Behav Neurol* 2001;14(4):246–247. [PMID: 11725219] (This bizarre finding has been described in previous case reports of MAO inhibitor overdose complicated by hyperthermia.)

► MUSHROOMS

Kathy Marquardt, PharmD

There are more than 5000 varieties of mushrooms in the United States, about 100 of which are potentially toxic. The majority of toxic mushrooms cause mild to moderate self-limited gastroenteritis. A few species may cause severe or even fatal reactions. The major categories of poisonous mushrooms are described in Table II–38. *Amanita phalloides* and other amatoxin-containing mushrooms are discussed on p 273.

- I. **Mechanism of toxicity.** The various mechanisms thought responsible for poisoning are listed in Table II–38. The majority of toxic incidents are caused by gastrointestinal irritants that produce vomiting and diarrhea shortly after ingestion.
- II. **Toxic dose.** This is not known. The amount of toxin varies considerably among members of the same species, depending on local geography and weather conditions. In most cases, the exact amount of toxic mushroom ingested is unknown because the victim has unwittingly added a toxic species to a meal of edible fungi.
- III. **Clinical presentation.** The various clinical presentations are described in Table II–38. In most cases, the onset of vomiting and diarrhea is rapid. A delay in onset of more than 6–12 hours suggests amatoxin, monomethylhydrazine, or orellanine poisoning.
- IV. **Diagnosis** may be difficult because the victim may not realize that the illness has been caused by mushrooms, especially if symptoms are delayed 12 or more hours

TABLE II-38. CLASSIFICATION OF MUSHROOM TOXICITY

Syndrome	Toxin(s)	Causative Mushrooms	Symptoms and Signs
Delayed gastroenteritis and liver failure	Amatoxins (See p 273)	<i>Amanita phalloides</i> , <i>A. ocreata</i> , <i>A. verna</i> , <i>A. virosa</i> , <i>A. bisporigera</i> , <i>Galerina autumnalis</i> , <i>G. marginata</i> , and some <i>Lepiota</i> and <i>Conocybe</i> species.	Delayed onset 6–24 h: vomiting, diarrhea, abdominal cramps, followed by fulminant hepatic failure after 2–3 days.
Delayed gastroenteritis, CNS abnormalities, hemolysis, hepatitis	Monomethylhydrazine	<i>Gyrometra (Helvella) esculenta</i> , others.	Delayed onset 6–12 h: vomiting, diarrhea, dizziness, weakness, headache, delirium, seizures, coma; hemolysis, methemoglobinemia, hepatic and renal injury may also occur.
Cholinergic syndrome	Muscarine	<i>Clitocybe dealbata</i> , <i>C. cerusata</i> , <i>Inocybe</i> , <i>Omphalotus olearius</i> .	Onset 30 min–2 h: diaphoresis, bradycardia, bronchospasm, lacrimation, salivation, sweating, vomiting, diarrhea, miosis. Treat with atropine (p 412).
Disulfiram-like reaction with alcohol	Coprine	<i>Coprinus atramentarius</i> , <i>Clitocybe clavipes</i> .	Within 30 min after ingestion of alcohol: nausea, vomiting, flushing, tachycardia, hypotension; risk of reaction for up to 5 days after ingesting fungi. (See Disulfiram, p 186).
Anticholinergic syndrome	Ibotenic acid, muscimol	<i>Amanita muscaria</i> , <i>A. pantherina</i> , others.	Onset 30 min–2 h: vomiting, followed by drowsiness, muscular jerking, hallucinations, delirium, psychosis. (See Anticholinergics, p 84).
Gastritis and renal failure	Allenic norleucine	<i>Amanita smithiana</i> .	Abdominal pain, vomiting within 30 min to 12 hours, followed by progressive acute renal failure within 2–3 days.
Delayed onset gastritis and renal failure	Orellanine	<i>Cortinarius orellanus</i> , other <i>Cortinarius</i> spp.	Abdominal pain, anorexia, vomiting starting after 24–36 hours, followed by progressive acute renal failure (tubulointerstitial nephritis) 3–14 days later.
Hallucinations	Psilocybin, psilocyn	<i>Psilocybe cubensis</i> , <i>Panaeolina foenicisecii</i> , others.	Onset 30 min–2 h: visual hallucinations, sensory distortion, tachycardia, mydriasis, occasionally seizures. (See also p 247).
Gastrointestinal irritants	Unidentified	<i>Chlorophyllum molybdites</i> , <i>Boletus satanas</i> , many others.	Vomiting, diarrhea within 30 min–2 h of ingestion.
Hemolytic anemia	Unknown	<i>Paxillus involutus</i> .	GI irritant for most, but a few people develop immune-mediated hemolysis within 2 h of ingestion.

after ingestion. If leftover mushrooms are available, obtain assistance from a mycologist through a local university or mycologic society. However, note that the mushrooms brought for identification may not be the same ones that were eaten.

A. Specific levels. Qualitative detection of the toxins of several mushroom species has been reported, but these tests are not routinely available.

B. Other useful laboratory studies include CBC, electrolytes, glucose, BUN, creatinine, liver transaminases, and prothrombin time (PT/INR). Obtain a methemoglobin level if gyrometrin-containing mushrooms are suspected or the patient is cyanotic.

V. Treatment

A. Emergency and supportive measures

1. Treat hypotension from gastroenteritis with intravenous crystalloid solutions (see p 16) and supine positioning. Treat agitation (p 24), hyperthermia (p 21), or seizures (p 22) if they occur.
2. Monitor patients for 12–24 hours for delayed-onset gastroenteritis associated with amatoxin or monomethylhydrazine poisoning.
3. Monitor renal function for 1–2 weeks after suspected *Cortinarius* spp ingestion, or 2–3 days after *Amanita smithiana* ingestion. Provide supportive care, including hemodialysis if needed, for renal dysfunction.

B. Specific drugs and antidotes

1. For **monomethylhydrazine** poisoning, give pyridoxine, 20–30 mg/kg IV (see p 499) for seizures; treat methemoglobinemia with methylene blue, 1 mg/kg IV (p 466).
2. For **muscarine** intoxication, atropine, 0.01–0.03 mg/kg IV (see p 412), may alleviate cholinergic symptoms.
3. **Ibotenic acid-induced** or **muscimol-induced** anticholinergic symptoms may improve with physostigmine (see p 489).
4. Treat **amatoxin-type** poisoning as described below.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. There is no accepted role for these procedures.

Lee PT et al: Rhabdomyolysis: an unusual feature with mushroom poisoning. *Am J Kidney Dis* 2001;38(4):E17. [PMID: 11576904] (An outbreak of severe rhabdomyolysis caused by *Russula subnigricans* in Taiwan.)

Mount P et al: Acute renal failure following ingestion of wild mushrooms. *Intern Med J* 2002;32(4):187–190. [PMID: 11951934] (Three cases of acute renal failure in Australia after ingestion of wild mushrooms with the intent of producing hallucinations. The causative mushrooms were not identified.)

► MUSHROOMS, AMATOXIN-TYPE

Kathy Marquardt, PharmD

Amatoxins (alpha-amanitin, mu-amanitin, and others) are a group of highly toxic peptides found in several species of mushrooms, including *Amanita phalloides*, *Amanita virosa*, *Amanita bisporigera*, *Amanita ocreata*, *Amanita verna*, *Galerina autumnalis*, *Galerina marginata*, and some species of *Lepiota* and *Conocybe*. These mushrooms

are often picked and eaten by amateur foragers who have misidentified them as an edible species.

- I. **Mechanism of toxicity.** Amatoxins are highly stable and resistant to heat and are not removed by any form of cooking. They are thought to act by inhibiting cellular protein synthesis by interfering with RNA polymerase.
 - A. Absorption of amatoxins (and phalloidins) by intestinal cells causes cell death and sloughing after a delay of 6–24 hours.
 - B. Absorption by the liver and kidneys results in severe hepatic necrosis and renal failure.
 - C. **Pharmacokinetics.** Amatoxins are readily absorbed from the intestine and are transported across the hepatocyte by bile transport carriers. About 60% undergoes enterohepatic recirculation. Toxins are detectable in urine within 90–120 minutes after ingestion. No metabolites of amatoxin have been detected. The half-life in humans is unknown, but there is a rapid decrease in serum levels with detection of toxin unlikely after 36 hours.
- II. **Toxic dose.** Amatoxins are among the most potent toxins known; the minimum lethal dose is about 0.1 mg/kg. One *Amanita* cap may contain 10–15 mg. In contrast, *Galerina* species contain far less toxin; 15–20 caps would be a fatal dose for an adult.
- III. **Clinical presentation.** The onset of symptoms is characteristically delayed 6–12 hours or even up to 24 hours after ingestion. Death occurring within the first 1–2 days is uncommon but may result from massive fluid loss due to gastroenteritis, while death occurring later is usually caused by hepatic failure.
 - A. **Gastroenteritis.** Initially, vomiting is accompanied by severe abdominal cramps and explosive watery diarrhea. Severe fluid losses and electrolyte imbalance can occur rapidly, and some patients die of shock within 24 hours.
 - B. **Hepatic failure.** Liver injury may be apparent within 24–36 hours, with rapidly rising transaminase levels. Fulminant hepatic failure may follow, with jaundice, encephalopathy, and death. Encephalopathy, metabolic acidosis, severe coagulopathy, and hypoglycemia are grave prognostic signs and usually predict a fatal outcome.
- IV. **Diagnosis** is usually based on a history of wild mushroom ingestion and a delay of 6–24 hours before onset of severe gastroenteritis (see also monomethylhydrazine-type mushrooms, Table II-38, p 272). However, if a variety of mushrooms have been eaten, stomach upset may occur much earlier owing to a different toxic species, making diagnosis of amatoxin poisoning more difficult.

Any available mushroom specimens that may have been ingested should be examined by a mycologist. Pieces of mushroom retrieved from the emesis or even mushroom spores found on microscopic examination may provide clues to the ingested species.

 - A. **Specific levels**
 1. Amatoxin can be detected in serum, urine, and gastric fluids by radioimmunoassay or HPLC but these methods are not readily available. Using HPLC, amatoxin has been detected in serum for up to 36 hours and urine for up to 4 days. Radioimmunoassay has detected amatoxins in urine in 100% of cases tested within 24 hours and in 80% of cases tested within 48 hours.
 2. A qualitative test (the Meixner test) may determine the presence of amatoxins in mushroom specimens. Juice from the mushroom is dripped onto newspaper or other unrefined paper and allowed to dry. A single drop of concentrated hydrochloric acid is then added; a blue color suggests the presence of amatoxins. **Caution:** This test has unknown reliability and can be misinterpreted or poorly performed; it should not be used to determine the edibility of mushroom specimens! In addition, false-positive reactions can be caused by drying at a temperature greater than 63°C, exposure of the test paper to sunlight, or the presence of psilocybin, bufotenin, or certain terpenes.

- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, bilirubin, and prothrombin time (PT/INR). Transaminases usually peak 60–72 hours after ingestion. Measures of liver function such as the INR are more useful in evaluating the severity of hepatic failure.
- V. Treatment.** The mortality rate is approximately 10–15% with intensive supportive care.
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Treat fluid and electrolyte losses aggressively, because massive fluid losses may cause circulatory collapse. Administer normal saline or another crystalloid solution, 10- to 20-mL/kg boluses, with monitoring of central venous pressure or even pulmonary artery pressure to guide fluid therapy.
 3. Provide vigorous supportive care for hepatic failure (p 40); orthotopic **liver transplantation** may be lifesaving in patients who develop fulminant hepatic failure. Contact a liver transplantation service for assistance.
- B. Specific drugs and antidotes.** There is no antidote that has been proved effective for amatoxin poisoning, although over the years many therapies have been promoted. Animal studies and retrospective comparisons in human cases suggest that early treatment with silibinin (an extract of the milk thistle, used in Europe intravenously in a dose of 20–50 mg/kg/day but not available as a pharmaceutical preparation in the United States; see p 500) or high doses of penicillin may partially protect against hepatic injury, but controlled human studies are lacking. There are no data to support the use of cimetidine or *N*-acetylcysteine. Consult a medical toxicologist or a regional poison control center ([800] 222-1222 in the United States) for further information.
- C. Decontamination** (see p 47)
1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 2. **Hospital.** Administer activated charcoal. Gastric lavage may not remove mushroom pieces.
- D. Enhanced elimination.** There is no proved role for forced diuresis, hemoperfusion, hemofiltration, or hemodialysis in the removal of amatoxins.
1. Repeat-dose activated charcoal may trap small quantities of amatoxin undergoing enterohepatic recirculation.
 2. Cannulation of the bile duct and removal of bile have been effective in dog studies.

► NAPHTHALENE AND PARADICHLOROBENZENE

Mark J. Galbo, MS

Naphthalene and paradichlorobenzene are common ingredients in diaper pail and toilet bowl deodorizers and moth repellants. Both compounds have a similar pungent odor and clear to white crystalline substances, and they are therefore difficult to dis-

tinguish visually. Naphthalene 10% in oil has been used as a scabicide in the past. Naphthalene is no longer commonly used because it has been largely replaced by the far less toxic paradichlorobenzene.

- I. **Mechanism of toxicity.** Both compounds cause gastrointestinal upset, and both may cause CNS stimulation. In addition, naphthalene may produce hemolysis, especially in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

II. **Toxic dose**

- A. **Naphthalene.** As little as one mothball containing naphthalene (250–500 mg) may produce hemolysis in a patient with G6PD deficiency. The amount necessary to produce lethargy or seizures is not known but may be as little as 1–2 g (4–8 mothballs). Several infants developed serious poisoning from clothes and bedding that had been stored in naphthalene mothballs.
- B. **Paradichlorobenzene** is much less toxic than naphthalene; up to 20-g ingestions have been well-tolerated in adults. The oral LD₅₀ for paradichlorobenzene in rats is 2.5–3.2 g/kg.
- C. **Pharmacokinetics.** Both compounds are rapidly absorbed orally or by inhalation.

- III. **Clinical presentation.** Acute ingestion usually causes prompt nausea and vomiting. Both compounds are volatile, and inhalation of vapors may cause eye, nose, and throat irritation.

- A. **Naphthalene.** Agitation, lethargy, and seizures may occur with naphthalene ingestion. Acute hemolysis may occur, especially in patients with G6PD deficiency. Chronic inhalation has also caused hemolytic anemia.
- B. **Paradichlorobenzene** ingestions are virtually always innocuous. Serious poisoning in animals is reported to cause tremors and hepatic necrosis. Paradichlorobenzene decomposes to hydrochloric acid, which may explain some of its irritant effects.

- IV. **Diagnosis** is usually based on a history of ingestion and the characteristic “mothball” smell around the mouth and in the vomitus. Differentiation between naphthalene and paradichlorobenzene by odor or color is difficult. In an in vitro x-ray study, paradichlorobenzene was radiopaque, but naphthalene was not visible. In a saturated salt solution (about 1 tablespoon of salt in 4 ounces of water) naphthalene will float and paradichlorobenzene will sink.

- A. **Specific levels.** Serum levels are not available.
- B. **Other useful laboratory studies** include CBC and, if hemolysis is suspected, haptoglobin, free hemoglobin, and urine dipstick for occult blood (positive with hemoglobinuria).

V. **Treatment**

A. **Emergency and supportive measures**

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19) and seizures (p 22) if they occur.
3. Treat hemolysis and resulting hemoglobinuria if they occur, by intravenous hydration and urinary alkalinization (see Rhabdomyolysis, p 27).

- B. **Specific drugs and antidotes.** There is no specific antidote.

C. **Decontamination** (see p 46)

1. **Naphthalene**

- a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of the risk of lethargy and seizures. Do not administer milk, fats, or oils, which may enhance absorption.
 - b. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
2. **Paradichlorobenzene.** Gut emptying and charcoal are not necessary unless a massive dose has been ingested. Do not administer milk, fats, or oils, which may enhance absorption.
 3. **Inhalation.** Either agent: remove the victim from exposure; fresh air is all that is required.

- D. **Enhanced elimination.** There is no role for these procedures.

Santucci K, Shah B: Association of naphthalene with acute hemolytic anemia. *Acad Emerg Med* 2000;7(1):42–47. [PMID: 10894241] (Hemolysis associated with exposure to naphthalene-containing mothballs was the most common emergency department presentation leading to diagnosis of G6PD deficiency in 24 African-American children.)

► NICOTINE

Neal L. Benowitz, MD

Nicotine poisoning may occur in children after they ingest tobacco or drink saliva expectorated by a tobacco chewer (which is often collected in a can or other containers); in children or adults after accidental or suicidal ingestion of nicotine-containing pesticides (such as Black Leaf 40, which contains 40% nicotine sulfate); and occasionally after cutaneous exposure to nicotine, such as among tobacco harvesters. Nicotine chewing gum (Nicorette), transdermal delivery formulations (Habitrol, Nicoderm, Nicotrol, Prostep, and generics), and nicotine nasal spray, inhalers, and lozenges are widely available as adjunctive therapy for smoking cessation. Alkaloids similar to nicotine (cytisine, coniine, and lobeline) are found in several plant species (see Plants, p 309)

I. Mechanism of toxicity

A. Nicotine binds to nicotinic cholinergic receptors, resulting initially, via actions on ganglia, in predominantly sympathetic nervous stimulation. With higher doses, parasympathetic stimulation and then ganglionic and neuromuscular blockage may occur. Direct effects on the brain may also result in vomiting and seizures.

B. Pharmacokinetics. Nicotine is rapidly absorbed by all routes. The apparent volume of distribution (V_d) is 3 L/kg. It is rapidly metabolized and to a lesser extent excreted in the urine, with a half-life of 120 minutes.

II. Toxic dose. Owing to presystemic metabolism and spontaneous vomiting, which limit absorption, the bioavailability of nicotine that is swallowed is about 30–40%. Rapid absorption of 2–5 mg can cause nausea and vomiting, particularly in a person who does not habitually use tobacco. Absorption of 40–60 mg in an adult is said to be lethal, although this dose spread throughout the day is not unusual in a cigarette smoker.

A. Tobacco. Cigarette tobacco contains about 1.5% nicotine, or 10–15 mg of nicotine per cigarette. Moist snuff is also about 1.5% nicotine; most containers hold 30 g of tobacco. Chewing tobacco contains 2.5–8% nicotine. In a child, ingestion of one cigarette or three cigarette butts should be considered potentially toxic, although serious poisoning from ingestion of cigarettes is very uncommon.

B. Nicotine gum contains 2 or 4 mg per piece, but owing to its slow absorption and high degree of presystemic metabolism, nicotine intoxication from these products is uncommon.

C. Transdermal nicotine patches deliver an average of 5–22 mg of nicotine over the 16–24 hours of intended application, depending on the brand and size. Transdermal patches may produce intoxication in light smokers or in non-smokers, particularly children to whom a used patch inadvertently sticks. Ingestion of a discarded patch may also potentially produce poisoning.

D. Nicotine nasal spray delivers about 1 mg (a single dose is one spray in each nostril).

E. Nicotine inhaler systems consist of a plastic mouthpiece and replaceable cartridges containing 10 mg of nicotine. If accidentally ingested, the cartridge would release the nicotine slowly and no serious intoxication has been reported.

F. Nicotine lozenges contain 2–4 mg nicotine, and ingestion could cause serious toxicity in a child.

III. Clinical presentation. Nicotine intoxication commonly causes dizziness, nausea, vomiting, pallor, and diaphoresis. Abdominal pain, salivation, lacrimation, and diarrhea may be noted. Pupils may be dilated or constricted. Confusion, agitation, lethargy, and convulsions are seen with severe poisonings. Initial tachycardia and hypertension may be followed by bradycardia and hypotension. Respiratory muscle weakness with respiratory arrest is the most likely cause of death. Symptoms usually begin within 15 minutes after acute liquid nicotine exposure and resolve in 1 or 2 hours, although more prolonged symptoms may be seen with higher doses or cutaneous exposure, the latter owing to continued absorption from the skin. Delayed onset and prolonged symptoms may also be seen with nicotine gum or transdermal patches.

IV. Diagnosis is suggested by vomiting, pallor, and diaphoresis, although these symptoms are nonspecific. The diagnosis is usually made by a history of tobacco, insecticide, or therapeutic nicotine product exposure. Nicotine poisoning should be considered in a small child with unexplained vomiting whose parents consume tobacco.

A. Specific levels. Nicotine or its metabolite cotinine are detected in comprehensive urine toxicology screens, but because these are so commonly present, they will not usually be reported unless specifically requested. Serum levels can be performed but are not useful in acute management.

B. Other useful laboratory studies include electrolytes, glucose, and arterial blood gases or oximetry.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat seizures (see p 22), coma (p 19), hypotension (p 16), hypertension (p 17), and arrhythmias (pp 10–15) if they occur.
3. Observe for at least 4–6 hours to rule out delayed toxicity, especially after skin exposure. For ingestion of intact gum tablets or transdermal patches, observe for a longer period (up to 12–24 hours).

B. Specific drugs and antidotes

1. **Mecamylamine** (Inversine) is a specific antagonist of nicotine actions; however, it is available only in tablets, a form not suitable for a patient who is vomiting, convulsing, or hypotensive.
2. Signs of muscarinic stimulation (bradycardia, salivation, wheezing, etc), if they occur, may respond to **atropine** (see p 412).

C. Decontamination (see p 46). **Caution:** Rescuers should wear appropriate skin-protective gear when treating patients with oral or skin exposure to liquid nicotine.

1. **Skin and eyes.** Remove all contaminated clothing and wash exposed skin with copious soap and water. Irrigate exposed eyes with copious saline or water.
2. **Ingestion** (see p 48). For asymptomatic small-quantity cigarette ingestions, no gut decontamination is necessary.
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures.
 - b. **Hospital.** Administer activated charcoal. Consider gastric lavage for large recent ingestions of liquid nicotine.
 - c. For ingestion of transdermal patches or large amounts of gum, consider repeated doses of charcoal and whole-bowel irrigation (see p 52).

D. Enhanced elimination. These procedures are not likely to be useful because the endogenous clearance of nicotine is high, its half-life is relatively short (2 hours), and the volume of distribution is large.

Davies P et al: Acute nicotine poisoning associated with a traditional remedy for eczema. *Arch Dis Child* 2001;85(6):500–502. [PMID: 11719343] (Case report of acute severe poisoning in an 8-year-old after topical application of a traditional remedy; serum nicotine was 89 ng/mL, and serum cotinine was 1430 ng/mL.)

► NITRATES AND NITRITES

Neal L. Benowitz, MD

Organic nitrates (eg, nitroglycerin, isosorbide dinitrate, and isosorbide mononitrate) are widely used as vasodilators for the treatment of ischemic heart disease and heart failure. Organic nitrates such as nitroglycerin are also used in explosives. Bismuth subnitrate, ammonium nitrate, and silver nitrate are used in antidiarrheal drugs, cold packs, and topical burn medications, respectively. Sodium and potassium nitrate and nitrite are used in preserving cured foods and may also occur in high concentrations in some well water. Butyl, amyl, ethyl, and isobutyl nitrites are often sold as “room deodorizers” or “liquid incense” and are sometimes inhaled for abuse purposes.

- I. **Mechanism of toxicity.** Nitrates and nitrites both cause vasodilation, which can result in hypotension.
 - A. **Nitrates** relax veins at lower doses and arteries at higher doses. Nitrates may be converted into nitrites in the gastrointestinal tract, especially in infants.
 - B. **Nitrites** are potent oxidizing agents. Oxidation of hemoglobin by nitrites may result in methemoglobinemia (see p 261), which hinders oxygen-carrying capacity and oxygen delivery. Many organic nitrites (eg, amyl nitrite and butyl nitrite) are volatile and may be inhaled.
- II. **Toxic dose.** In the quantities found in food, nitrates and nitrites are generally not toxic; however, infants may develop methemoglobinemia after ingestion of sausages or well water because they readily convert nitrate to nitrite and because their hemoglobin is more susceptible to oxidation compared with that of adults.
 - A. **Nitrates.** The estimated adult lethal oral dose of nitroglycerin is 200–1200 mg. Hypotension occurs at low doses, but massive doses are required to produce methemoglobinemia.
 - B. **Nitrites.** Ingestion of as little as 15 mL of butyl nitrite produced 40% methemoglobinemia in an adult. The estimated adult lethal oral dose of sodium nitrite is 1 g.
- III. **Clinical presentation.** Headache, skin flushing, and orthostatic hypotension with reflex tachycardia are the most common adverse effects of nitrates and nitrites and occur commonly even with therapeutic doses of organic nitrates.
 - A. **Hypotension** may aggravate or produce symptoms of cardiac ischemia or cerebrovascular disease and may even cause seizures. However, fatalities from hypotension are rare.
 - B. Workers or patients regularly exposed to nitrates may develop tolerance and may suffer **angina** or **myocardial infarction** owing to rebound coronary vasoconstriction upon sudden withdrawal of the drug.
 - C. **Methemoglobinemia** (see p 261) is most common after nitrite exposure; the skin is cyanotic, even at levels low enough to be otherwise asymptomatic (eg, 15%).
 - D. Use of **sildenafil** (Viagra™) can prolong and intensify the vasodilating effects of nitrates, causing severe hypotension.
- IV. **Diagnosis** is suggested by hypotension with reflex tachycardia and headache. Methemoglobinemia of 15% or more may be diagnosed by noting a chocolate brown coloration of the blood when it is dried on filter paper.
 - A. **Specific levels.** Blood levels are not commercially available. With the use of a nitrite dipstick (normally used to detect bacteria in urine), nitrite can be detected in the serum of patients intoxicated by alkyl nitrites.
 - B. **Other useful laboratory studies** include electrolytes, glucose, arterial blood gases or oximetry, methemoglobin concentration, and ECG and ECG monitoring.
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Treat hypotension with supine positioning, intravenous crystalloid fluids, and low-dose pressors if needed (see p 16).

3. Monitor vital signs and ECG for 4–6 hours.
- B. Specific drugs and antidotes.** Symptomatic methemoglobinemia may be treated with **methylene blue** (see p 466).
- C. Decontamination** (see p 46)
 1. **Inhalation.** Remove victims from exposure and administer supplemental oxygen if available.
 2. **Skin and eyes.** Remove contaminated clothing and wash with copious soap and water. Irrigate exposed eyes with water or saline.
 3. **Ingestion** (see p 48)
 - a. **Prehospital.** Administer activated charcoal if available.
 - b. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary for small ingestions if activated charcoal can be given promptly.
- D. Enhanced elimination.** Hemodialysis and hemoperfusion are not effective. Severe methemoglobinemia in infants not responsive to methylene blue therapy may require **exchange transfusion**.

Methemoglobinemia following unintentional ingestion of sodium nitrite—New York, 2002. *MMWR* 2002;51(29):639–642. [PMID: 12186221] (Five members of a household developed methemoglobinemia after eating a meal seasoned with sodium nitrite labeled as table salt.)

► NITROGEN OXIDES

Paul D. Blanc, MD, MSPH

Nitrogen oxides (nitric oxide or nitrogen dioxide; *not* nitrous oxide [p 282]) are gases commonly released from nitrous or nitric acid, from reactions between nitric acid and organic materials, and from burning of nitrocellulose and many other products. Exposure to nitrogen oxides occurs in electric arc welding, electroplating, and engraving. Nitrogen oxides are found in engine exhaust, and they are produced when stored grain with a high nitrite content ferments in storage silos. Nitric oxide used as a therapeutic agent reacts with oxygen to form nitrogen dioxide.

- I. Mechanism of toxicity.** Nitrogen oxides are irritant gases with relatively low water solubility causing delayed onset of chemical pneumonitis. In addition, nitrogen oxides can oxidize hemoglobin to methemoglobin.
- II. Toxic dose.** The ACGIH-recommended workplace exposure limit (threshold limit value; TLV-TWA) for nitric oxide is 25 ppm (31 mg/m³), and for nitrogen dioxide it is 3 ppm (5.6 mg/m³) as an 8-hour time-weighted average. The air levels considered immediately dangerous to life or health (IDLH) are 100 and 20 ppm, respectively.
- III. Clinical presentation.** Because of the poor water solubility of nitrogen oxides, there is very little upper respiratory irritation at low levels (< 10 ppm nitrogen dioxide), allowing prolonged exposure with no warning symptoms other than mild cough or nausea. With more concentrated exposures, upper respiratory symptoms such as burning eyes, sore throat, and cough may occur.
 - A.** After a delay of up to 24 hours, chemical pneumonitis may develop, with progressive hypoxemia and pulmonary edema. The onset may be more rapid after exposure to higher concentrations. Some cases may evolve to bronchiolitis obliterans.
 - B.** After recovery from acute chemical pneumonitis and after chronic low-level exposure to nitrogen oxides, permanent lung disease from bronchiolar damage may become evident.
 - C.** Methemoglobinemia has (see p 261) been described in victims exposed to nitrogen oxides in smoke during major structural fires.
 - D.** Inhaled nitric oxide (eg, used for therapeutic purposes as a pulmonary vasodilator in neonates) can have extrapulmonary effects, including reduced platelet aggregation, methemoglobinemia, and systemic vasodilation.

IV. Diagnosis is based on a history of exposure, if known. Because of the potential for delayed effects, all patients with significant smoke inhalation should be observed for several hours.

A. Specific levels. There are no specific blood levels.

B. Other useful laboratory studies include arterial blood gases or oximetry, methemoglobin level, chest x-ray, and pulmonary function tests.

V. Treatment

A. Emergency and supportive measures

1. Observe closely for signs of upper-airway obstruction, and intubate the trachea and assist ventilation if necessary (see pp 1–7). Administer humidified supplemental oxygen.
2. Observe symptomatic victims for a minimum of 24 hours after exposure and treat chemical pneumonia and noncardiogenic pulmonary edema (see p 7) if they occur.

B. Specific drugs and antidotes

1. Administration of corticosteroids has been recommended. Although they may not reverse acute nitrogen oxide–induced chemical pneumonitis, they are effective for bronchiolitis obliterans.
2. Treat methemoglobinemia with **methylene blue** (see p 466).

C. Decontamination (see p 46). Rescuers should wear self-contained breathing apparatus, and if there is the potential for high-level gas exposure or exposure to liquid nitric acid, chemical-protective clothing.

1. **Inhalation.** Remove victims from exposure immediately and give supplemental oxygen, if available.
2. **Skin and eyes.** Remove any wet clothing, and flush exposed skin with water. Irrigate exposed eyes with copious water or saline.

D. Enhanced elimination. There is no role for enhanced elimination procedures.

Weinberger B et al: The toxicology of inhaled nitric oxide. *Toxicol Sci* 2001;59(1):5–16. [PMID: 11134540] (In addressing nitric oxide, this review also provides an excellent summary of the effects of nitrogen dioxide.)

► NITROPRUSSIDE

Neal L. Benowitz, MD

Sodium nitroprusside is a short-acting parenterally administered vasodilator used to treat severe hypertension and cardiac failure. It is also used to induce hypotension for certain surgical procedures. Toxicity may occur with acute high-dose nitroprusside treatment or with prolonged infusions.

I. Mechanism of toxicity. Nitroprusside is rapidly hydrolyzed (half-life 11 minutes) and releases free cyanide, which is normally quickly converted to thiocyanate by rhodanase enzymes in the liver and blood vessels.

A. Acute cyanide poisoning (see p 177) may occur with short-term high-dose nitroprusside infusions (eg, > 10–15 mcg/kg/min for 1 hour or longer).

B. Thiocyanate is eliminated by the kidney and may accumulate in patients with renal insufficiency, especially after prolonged infusions.

II. Toxic dose. The toxic dose depends on renal function and the rate of infusion.

A. Cyanide poisoning is uncommon at nitroprusside infusion rates of less than 8–10 mcg/kg/min, but has been reported after infusion of 4 mcg/kg/min for 3 hours.

B. Thiocyanate toxicity does not occur with acute brief use in persons with normal renal function, but may result from prolonged infusions (eg, > 3 mcg/kg/min for 48 hours or longer), especially in persons with renal insufficiency (with rates as low as 1 mcg/kg/min).

- III. Clinical presentation.** The most common adverse effect of nitroprusside is hypotension, which is often accompanied by reflex tachycardia. Peripheral and cerebral hypoperfusion can lead to lactic acidosis and altered mental status.
- A. Cyanide** poisoning is accompanied by headache, hyperventilation, anxiety, agitation, seizures, and metabolic acidosis. The ECG may reveal ischemic patterns.
- B. Thiocyanate** accumulation causes somnolence, confusion, delirium, tremor, and hyperreflexia. Seizures and coma may rarely occur with severe toxicity.
- C.** Methemoglobinemia occurs rarely and is usually mild.
- IV. Diagnosis.** Lactic acidosis, coma, or seizures after short-term high-dose nitroprusside infusion should suggest cyanide poisoning, while confusion or delirium developing gradually after several days of continuous use should suggest thiocyanate poisoning.
- A. Specific levels.** Cyanide levels may be obtained but are not usually available rapidly enough to guide treatment when cyanide poisoning is suspected. Cyanide levels may not accurately reflect toxicity because of simultaneous production of methemoglobin, which binds some of the cyanide. Cyanide levels greater than 1 mg/L usually produce a demonstrable lactic acidosis. **Thiocyanate** levels higher than 50–100 mg/L may cause delirium and somnolence.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, serum lactate, ECG, arterial blood gases and measured arterial and venous oxygen saturation (see Cyanide, p 177), and methemoglobin level.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. For hypotension, stop the infusion immediately and administer intravenous fluids or even pressors if necessary (see p 16).
- B. Specific drugs and antidotes.** If cyanide poisoning is suspected, administer **sodium thiosulfate** (see p 505). Sodium nitrite treatment may aggravate hypotension and should not be used. **Hydroxocobalamin** (p 453), 25 mg/h IV infusion, is sometimes coadministered with high-dose nitroprusside as prophylaxis against cyanide toxicity.
- C. Decontamination.** These procedures are not relevant because the drug is administered only parenterally.
- D. Enhanced elimination.** Nitroprusside and cyanide are both metabolized rapidly, so there is no need to consider enhanced elimination for these. Hemodialysis may accelerate **thiocyanate** elimination and is especially useful in patients with renal failure.

Froldi R et al: A case of suicide by ingestion of sodium nitroprusside. *J Forensic Sci* 2001;46(6):1504–1506. [PMID: 11714168] (Case report of an unusual overdose.)

► NITROUS OXIDE

Aaron Schneir, MD

Nitrous oxide, or laughing gas, is used as an adjuvant for general anesthesia, as an anesthetic and analgesic agent for minor procedures, and as a propellant in many commercial products such as whipped cream or cooking oil spray. (“Whippets” are small cartridges of nitrous oxide that can be purchased at restaurant supply stores, grocery convenience stores, or “head shops.”) Nitrous oxide is used by many US dentists, in some cases without adequate scavenging equipment. Abuse of nitrous oxide is not uncommon in the medical and dental professions.

I. Mechanism of toxicity

- A. Acute toxicity** after exposure to nitrous oxide is mainly caused by asphyxia if adequate oxygen is not supplied with the gas.

- B. Chronic toxicity** to the hematologic and nervous systems results from inactivation of vitamin B₁₂ following irreversible oxidation of its cobalt atom. Vitamin B₁₂ is required for the synthesis of methionine, which is essential for DNA synthesis and maintenance of myelin. Use of nitrous oxide can precipitate neurological symptoms in patients with subclinical B₁₂ or folic acid deficiency.
- C. Adverse reproductive** outcomes have been reported in workers chronically exposed to nitrous oxide.
- II. Toxic dose.** The toxic dose is not established. Chronic occupational exposure to 2000 ppm nitrous oxide produced asymptomatic but measurable depression of vitamin B₁₂ in dentists. The ACGIH-recommended workplace exposure limit (TLV-TWA) is 50 ppm (90 mg/m³) as an 8-hour time-weighted average.
- III. Clinical presentation**
- A.** Signs of **acute toxicity** are related to **asphyxia**. These include headache, dizziness, confusion, syncope, seizures, and cardiac arrhythmias. Interstitial emphysema and pneumomediastinum have been reported after forceful inhalation from a pressurized whipped cream dispenser.
- B. Chronic nitrous oxide abuse** may produce megaloblastic anemia, thrombocytopenia, leukopenia, peripheral neuropathy (especially posterior column findings), and myelopathy, similar to the effects of vitamin B₁₂ deficiency.
- IV. Diagnosis** is based on a history of exposure and clinical presentation (eg, evidence of asphyxia and an empty can or tank). It should also be considered in a patient with manifestations suggesting chronic vitamin B₁₂ deficiency but with normal vitamin B₁₂ levels.
- A. Specific levels.** Specific levels are not generally available and are unreliable owing to off-gassing.
- B. Other useful laboratory studies** include CBC with manual differential, vitamin B₁₂, folic acid, nerve conduction studies, and MRI if the patient has neuropathy.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer high-flow supplemental oxygen.
 2. After significant asphyxia, anticipate and treat coma (see p 19), seizures (p 22), and cardiac arrhythmias (pp 10–15).
- B. Specific drugs and antidotes.** Chronic effects may resolve over 2–3 months after discontinuing exposure. Successful treatment with methionine has been reported.
- C. Decontamination.** Remove victims from exposure and give supplemental oxygen if available.
- D. Enhanced elimination.** These procedures are not effective.

Butzkueven H, King JO: Nitrous oxide myelopathy in an abuser of whipped cream bulbs. *J Clin Neurosci* 2000;7(1):73–75. [PMID: 10847659] (Case report with severe posterior column myelopathy, treated with methionine and vitamin B₁₂.)

Deleu D et al: Long-term effects of nitrous oxide anaesthesia on laboratory and clinical parameters in elderly Omani patients: a randomized double-blind study. *J Clin Pharm Ther* 2000;25(4):271–277. [PMID: 10971777] (Some patients with preexisting asymptomatic folate deficiency developed acute folate deficiency and reduced folic acid levels after 40–80 minutes of nitrous oxide anesthesia.)

► NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Winnie W. Tai, PharmD

The nonsteroidal anti-inflammatory drugs (NSAIDs) are a chemically diverse group of agents that share similar pharmacologic properties and are widely used for control of pain and inflammation (Table II–39). Overdose by most of the agents in this group usually produces only mild gastrointestinal upset. However, toxicity may be more se-

TABLE II-39. COMMON NSAIDs

Drug	Maximum Daily Adult Dose (mg)	Half-Life (h)	Comments
Carboxylic acids			
Bromfenac sodium	150	1-2	Chronic use associated with severe liver injury.
Carprofen	1 mg/kg		Approved for use in dogs only.
Diclofenac	200	2	
Diffunisal	1500	8-12	
Etodolac	1000	7	
Fenoprofen	3200	3	Acute renal failure.
Ibuprofen ^a	3200	2-4	Massive overdose may cause coma, renal failure, metabolic acidosis, and cardiorespiratory depression.
Indomethacin	200	3-11	
Ketoprofen ^a	300	2-4	Large overdoses may cause respiratory depression, coma, seizures.
Ketorolac	40 (PO) 60-120 (IV)	4-6	High risk of renal failure.
Meclofenamate	400	1-3	
Mefenamic acid	1000	2	Seizures, twitching.
Naproxen ^a	1500	12-17	Seizures, acidosis.
Oxaprozin	1800	42-50	
Sulindac	400	7-16	Extensive enterohepatic recirculation.
Tolmetin	1800	1	
Enolic acids			
Nabumetone	2000	24	
Oxyphenbutazone	600	27-64	Seizures, acidosis.
Phenylbutazone	600	50-100	Seizures, acidosis.
Piroxicam	20	45-50	Seizures, coma.
Meloxicam	15	15-20	
COX-2 inhibitors			Toxicity of this new group of drugs after overdose is unknown.
Celecoxib	400	11	
Rofecoxib	50	17	
Parecoxib			Prodrug for valdecoxib; IM/IV use only; investigational in United States.
Valdecoxib	40	8-11	

^aCurrently available in the United States as nonprescription formulations.

vere after overdose with **oxyphenbutazone, phenylbutazone, mefenamic acid, piroxicam, or diflunisal.**

I. Mechanism of toxicity

A. NSAIDs produce their pharmacologic and most toxicologic effects by inhibiting the enzyme cyclooxygenase (isoforms COX-1 and COX-2); this results in decreased production of prostaglandins and decreased pain and inflammation. CNS, hemodynamic, pulmonary, and hepatic dysfunction also occur with some agents, but the relationship to prostaglandin production remains uncertain. Prostaglandins are also involved in maintaining the integrity of the gastric

mucosa and regulating renal blood flow; thus, acute or chronic intoxication may affect these organs.

- B. The newest generation of NSAIDs, known as the COX-2 inhibitors (rofecoxib, or VioxxTM; celecoxib, or CelebrexTM), selectively inhibit the cyclooxygenase-2 isoform with no COX-1 inhibition at therapeutic doses. Since COX-1 is involved in GI mucosal protection, these drugs reduce the likelihood of GI bleeding compared to conventional NSAIDs.
 - C. **Pharmacokinetics.** NSAIDs are generally well absorbed, and volumes of distribution (Vd) are relatively small (eg, 0.15 L/kg for ibuprofen). COX-2 inhibitors have larger volumes of distribution (86–91 L in adults for rofecoxib, 400 L for celecoxib). Most agents are highly protein bound, and most are eliminated through hepatic metabolism and renal excretion with variable half-lives (eg, 1.5–2.5 hours for ibuprofen and 12–17 hours for naproxen). (See also Table II–59.)
- II. **Toxic dose.** Human data are insufficient to establish a reliable correlation between amount ingested, plasma concentrations, and clinical toxic effects. Generally, significant symptoms occur after ingestion of more than 5–10 times the usual therapeutic dose.
- III. **Clinical presentation.** In general, patients with NSAID overdose are asymptomatic or have mild gastrointestinal upset (nausea, vomiting, abdominal pain, sometimes hematemesis). Occasionally patients exhibit drowsiness, lethargy, ataxia, nystagmus, tinnitus, and disorientation.
- A. With the more toxic agents **oxyphenbutazone, phenylbutazone, mefenamic acid, or piroxicam**, and with massive **ibuprofen** or **fenoprofen** overdose, seizures, coma, renal failure, and cardiorespiratory arrest may occur. Hepatic dysfunction, hypoprothrombinemia, and metabolic acidosis are also reported.
 - B. **Diflunisal** overdose produces toxicity resembling salicylate poisoning (see p 331).
 - C. Chronic use of **bromfenac** for more than 10 days has resulted in fatal hepatotoxicity.
 - D. **Phenylbutazone** and **antipyrine** use have been associated with agranulocytosis and other blood dyscrasias.
 - E. There is limited information regarding overdoses of COX-2 inhibitors. The manufacturers of rofecoxib and celecoxib speculate that hypertension, acute renal failure, respiratory depression, and coma might occur in overdose.
- IV. **Diagnosis** is usually based primarily on a history of ingestion of NSAIDs, because symptoms are mild and nonspecific and quantitative levels are not usually available.
- A. **Specific levels** are not usually readily available and do not contribute to clinical management.
 - B. **Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, liver transaminases, prothrombin time (PT/INR), and urinalysis.
- V. **Treatment**
- A. **Emergency and supportive measures**
 - 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 - 2. Treat seizures (see p 22), coma (p 19), and hypotension (p 16) if they occur.
 - 3. Antacids may be used for mild gastrointestinal upset. Replace fluid losses with intravenous crystalloid solutions.
 - B. **Specific drugs and antidotes.** There is no antidote. Vitamin K (see p 508) may be used for patients with elevated prothrombin time (PT) caused by hypoprothrombinemia.
 - C. **Decontamination** (see p 47)
 - 1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary for most ingestions if activated charcoal can be given promptly. Consider gastric lavage for massive overdoses.
- D. **Enhanced elimination.** NSAIDs are highly protein bound and extensively metabolized. Thus, hemodialysis, peritoneal dialysis, and forced diuresis are not likely to be effective.
 1. **Charcoal hemoperfusion** may be effective for **phenylbutazone** overdose, although there are limited clinical data to support its use.
 2. Repeat-dose activated charcoal therapy may enhance the elimination of meloxicam, oxyphenbutazone, phenylbutazone, and piroxicam.
 3. Repeated oral doses of cholestyramine have been reported to increase the clearance of meloxicam and piroxicam.

Seifert SA et al: Massive ibuprofen ingestion with survival. *J Toxicol Clin Toxicol* 2000;38(1): 55–57. [PMID: 10696926] (Ingestion of 100 g resulted in coma, metabolic acidosis, and mild thrombocytopenia, but the patient improved rapidly with supportive care.)

► NONTOXIC OR MINIMALLY TOXIC HOUSEHOLD PRODUCTS

Eileen Morentz and Jay Schrader

There are a variety of products commonly found around the home that are either completely nontoxic or have little or no toxicity after typical accidental exposures. Treatment is rarely required because the ingredients are not toxic, the concentrations of potentially toxic ingredients are minimal, or the construction or packaging of the product is such that a significant dose of a harmful ingredient is extremely unlikely.

Table II–40 lists a number of products considered nontoxic. However, the taste or texture of the product may be disagreeable or cause mild stomach upset. Also, some of the products listed can create a foreign body effect or a choking hazard depending on the formulation and the age of the child. Table II–41 provides examples of products that may cause mild gastrointestinal upset but are generally not considered toxic after small ingestions. Stomach cramps, vomiting, or diarrhea may occur but is usually mild and self-limited. Table II–42 lists several other products that are often ingested by small children with minimal effect. While they may contain potentially toxic ingredients, the concentrations or packaging makes it very unlikely that symptoms will occur after a small exposure.

In all cases involving exposures to these substances, attempt to confirm the identity and/or ingredients of the product and assure that no other more toxic products were involved. Determine whether there are any unexpected symptoms or evidence of choking or foreign body effect. Advise the parent that mild gastrointestinal upset may occur. Water or other liquid may be given to reduce the taste or texture of the product. For symptomatic eye exposures, follow the instructions for ocular decontamination (see p 47).

Annual Reports of the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers: <http://www.aapcc.org/annual.htm> (Yearly reports 1983–present of poisoning exposures in the United States.)

► OPIATES AND OPIOIDS

Timothy E. Albertson, MD, PhD

Opiates are a group of naturally occurring compounds derived from the juice of the poppy *Papaver somniferum*. Morphine is the classic opiate derivative used widely in medicine; heroin (diacetylmorphine) is a well-known, highly addictive street narcotic.

TABLE II-40. NONTOXIC OR MINIMALLY TOXIC PRODUCTS^a

Air fresheners	Diapers, disposable	Plastic
Aluminum foil	Erasers	Playdoh
Antiperspirants	Eye makeup	Putty
Ashes, wood/fireplace	Felt-tip markers and pens	Rouge
Aspartame	Fingernail polish (dry)	Rust
Baby lotion (Note: baby oil can cause aspiration pneumonitis; see p 219)	Glitter	Saccharin
Baby powder (without talc)	Glow stick/jewelry	Shellac (dry)
Baby wipes	Gum	Sheetrock
Ball-point pen ink	Gypsum	Shoe polish
Calamine lotion	Incense	Silica gel
Candles	Indelible markers	Silly putty
Chalk ^b	Ink (w/out aniline dyes)	Soil
Charcoal	Kitty litter	Stamp pad ink
Charcoal briquettes	Lip balm	Starch
Cigarette ashes	Lipstick	Styrofoam
Cigarette filter tips (unsmoked)	Magic markers	Superglue
Clay	Makeup	Teething rings
Cold packs (for large ingestions, see Nitrates, p 279)	Mascara	Thermometers (phthalates/alcohol, gallium)
Crayons	Matches (< 3 paper books)	Wall board
Cyanoacrylate glues	Mylar balloons	Watercolor paints
Deodorants	Newspaper	Wax
Desiccants	Paraffin	Zinc oxide ointment
	Pencils (contain graphite, not lead)	
	Photographs	
	Plaster	

^aThese items are virtually nontoxic in small to moderate exposures. However, the taste or texture of the product may result in mild stomach upset. In addition, some of the products may cause a foreign body effect or choking hazard depending on the size of the product and the age of the child.

^bPlain drawing chalk. (Old pool-cue chalk may contain lead. “Chinese chalk” contains pyrethrins.)

The term *opioids* refers to these and other derivatives of naturally occurring opium (eg, morphine, heroin, codeine, and hydrocodone) as well as new, totally synthetic opiate analogs (eg, fentanyl, butorphanol, meperidine, and methadone Table II-43). A wide variety of prescription medications contain opioids, often in combination with aspirin or acetaminophen. **Dextromethorphan** (see p 183) is an opioid derivative with potent antitussive but no analgesic or addictive properties. **Tramadol** (Ultram™)

TABLE II-41. MILD GASTROINTESTINAL IRRITANTS^a

A & D ointment	Corticosteroids	Lanolin
Antacids	Dishwashing liquid soaps (not electric dishwashing type)	Latex paint
Antibiotic ointments	Fabric softeners	Liquid soaps
Baby bath	Fertilizers (nitrogen, phosphoric acid, and potash)	Miconazole
Baby shampoo	Glycerin	Petroleum jelly
Bar soap	Guaifenesin	Plant food
Bath oil beads	Hair conditioners	Prednisone
Bleach (household, less than 6% hypochlorite)	Hair shampoos	Shaving cream
Body lotions and creams	Hand soaps	Simethicone
Bubble bath	Hydrocortisone cream	Spermicides (nonoxynol-9 < 10%)
Bubbles	Hydrogen peroxide 3%	Steroid creams
Carbamide peroxide 6.5%	Kaolin	Sunscreen/suntan lotions (allergic reactions possible)
Chalk (calcium carbonate)	Lactase	Toothpaste (without fluoride)
Clotrimazole cream		

^aThe items in this list usually have little or no effect in small ingestions. In moderate to large ingestions, gastrointestinal effects such as diarrhea, constipation, stomach cramps, or vomiting may occur. The effects are usually mild and rarely require medical intervention.

TABLE II-42. OTHER LOW-TOXICITY PRODUCTS^a

Products	Comments
Holiday hazards	
Angel hair	Finely spun glass. Dermal or ocular irritation or corneal abrasion is possible.
Bubble lights	May contain a tiny amount of methylene chloride.
Christmas tree ornaments	Can cause foreign body effect or choking hazard. Antique or foreign-made ornaments may be decorated with lead-based paint.
Christmas tree preservatives	Homemade solutions may contain aspirin, bleach, or sugar. Commercial products usually contain only concentrated sugar solution.
Easter egg dyes	Most of these contain nontoxic dyes and sodium bicarbonate. Older formulations may contain sodium chloride, which can cause hypernatremia if a large amount is ingested (see p 35).
Fireplace crystals	May contain salts of copper, selenium, arsenic, and antimony. Small amounts can cause irritation to the mouth or stomach. (Larger ingestions could conceivably result in heavy metal poisoning; see specific heavy metal.)
Halloween candy	Tampering rarely occurs. X-ray of candy provides a false sense of security; although it may reveal radiopaque glass or metallic objects, most poisons are radiolucent. Prudent approach is to discard candy or food items that are not commercially packaged or if the package is damaged.
Snow scenes	The "snow" is comprised of insoluble particles of calcium carbonate that are not toxic. The fluid may have bacterial growth.
Snow sprays	Sprays may contain hydrocarbon solvent or methylene chloride (see pp 219 and 265) vehicle. Inhalation may cause headache and nausea. Once dried, the snow is not toxic.
Miscellaneous	
Capsaicin sprays	These products contain capsaicin, the main ingredient in chili peppers. Exposure causes intense mucous membrane irritation and burning sensation. Treat with topical liquid antacids.
Cyanoacrylate glues	Ingestion is harmless. Cyanide is not released. Corneal abrasions may occur following ocular exposure. Adhesion of skin and eyelids is possible following dermal exposure. Treat adhesions with petrolatum-based ointment.
Fire extinguishers	The two common types contain sodium bicarbonate (white powder) or monoammonium phosphate (yellow powder). Small ingestions result in little or no effect. Mucous membrane irritation is common. Major risk is pneumonitis after extensive inhalation.
Fluorescent light bulbs	Contain inert gases and nontoxic powder that may be irritating to mucous membranes.
Oral contraceptives	Birth control pills contain varying amounts of estrogens and progestones. In excessive amounts these may cause stomach upset, and in females (even prepubertal) may cause transient vaginal spotting. Some formulations may contain iron.
Thermometers (mercury)	Household fever thermometers contains less than 0.5 mL liquid mercury, which is harmless if swallowed. Clean up cautiously to avoid dispersing Hg as mist or vapor (ie, do not vacuum).
Household pesticides	
	Numerous formulations; some contain hydrocarbon solvents, others are water-based. Pesticides used may include pyrethrins, organophosphates, or carbamates, but generally low potency and in concentrations less than 1.5%. The risk of pesticide poisoning is very low unless intentional massive exposure. Symptoms after exposure mainly due to inhalation of the hydrocarbon solvent.
Topical monthly flea control products	Formulations include fipronil, imidacloprid. Low oral toxicity following ingestion of less than 2–3 mL. Dermal and ocular irritation may occur.
Respiratory irritants	
Baby powders (talco-containing), starch	These products have little or no toxicity when ingested. However, if aspirated into the lungs, they can cause an inflammatory pneumonitis.

^aThese products may contain small amounts of potentially toxic ingredients, but rarely cause problems because of the small concentrations or conditions of exposure.

TABLE II-43. COMMON OPIATES AND OPIOIDS^a

Drug	Type of Activity	Usual Adult Dose ^a (mg)	Elimination Half-Life (h)	Duration of Analgesia (h)
Butorphanol	Mixed	2	5–6	3–4
Codeine	Agonist	60	2–4	4–6
Fentanyl	Agonist	0.2	1–5	0.5–2
Heroin ^b	Agonist	4	(b)	3–4
Hydrocodone	Agonist	5	3–4	4–8
Hydromorphone	Agonist	1.5	1–4	4–5
Meperidine	Agonist ^c	100	2–5	2–4
Methadone	Agonist	10	20–30	4–8 ^d
Morphine	Agonist	10	2–4	3–6
Nalbuphine	Mixed	10	5	3–6
Oxycodone	Agonist	4.5	2–5	4–6
Pentazocine	Mixed	50	2–3	2–3
Propoxyphene	Agonist	100	6–12	4–6
Tramadol	Agonist ^c	50–100	6–7.5	4–6

^aUsual dose: Dose equivalent to 10 mg of morphine.^bRapidly hydrolyzed to morphine.^cAlso inhibits serotonin reuptake.^dSedation and coma may last 2–3 days.

is a newer analgesic that is unrelated chemically to the opiates but acts on *mu* opioid receptors and blocks serotonin reuptake. **Butorphanol** is available as a nasal spray with rapid absorption.

I. Mechanism of toxicity

A. In general, opioids share the ability to stimulate a number of specific opiate receptors in the CNS, causing sedation and respiratory depression. Death results from respiratory failure, usually as a result of apnea or pulmonary aspiration of gastric contents. In addition, acute noncardiogenic pulmonary edema may occur by unknown mechanisms.

B. Pharmacokinetics. Usually, peak effects occur within 2–3 hours, but absorption may be slowed by their pharmacologic effects on gastrointestinal motility. Most drugs have large volumes of distribution (3–5 L/kg). The rate of elimination is highly variable, from 1–2 hours for fentanyl derivatives versus 15–30 hours for methadone. See also Tables II-43 and II-59.

II. Toxic dose. The toxic dose varies widely depending on the specific compound, the route and rate of administration, and the tolerance to the effects of the drug as a result of chronic use. Some newer fentanyl derivatives have a potency up to 2000 times that of morphine.

III. Clinical presentation

A. With mild or moderate overdose, lethargy is common. The pupils are usually small, often “pinpoint” size. Blood pressure and pulse rate are decreased, bowel sounds are diminished, and the muscles are usually flaccid.

B. With higher doses, coma is accompanied by respiratory depression, and apnea often results in sudden death. Noncardiogenic pulmonary edema may occur, often after resuscitation and administration of the opiate antagonist naloxone.

C. Seizures are not common after opioid overdose but occur occasionally with certain compounds (eg, dextromethorphan, meperidine, propoxyphene, and tramadol). Seizures may occur in patients with renal compromise who receive

repeated doses of meperidine, owing to accumulation of the metabolite normeperidine.

- D. **Cardiotoxicity** similar to that seen with tricyclic antidepressants (see p 90) and quinidine (p 324) can occur in patients with severe **propoxyphene** intoxication.
 - E. Some newer synthetic opioids have mixed agonist and antagonist effects with unpredictable results in overdose.
 - F. Opioid **withdrawal syndrome** can cause anxiety, piloerection (goosebumps), abdominal cramps and diarrhea, and insomnia.
- IV. **Diagnosis** is simple when typical manifestations of opiate intoxication are present (pinpoint pupils and respiratory and CNS depression), and the patient quickly awakens after administration of naloxone. Signs of intravenous drug abuse (eg, needle track marks) may be present.
- A. **Specific levels** are not usually performed because of poor correlation with clinical effects. Qualitative screening of the urine is an effective way to confirm recent use. Fentanyl derivatives, tramadol, and some other synthetic opioids may not be detected by routine toxicologic screens (see Table I-31, p 42).
 - B. **Other useful laboratory studies** include electrolytes, glucose, arterial blood gases or oximetry, chest x-ray, and stat serum acetaminophen or salicylate levels (if the ingested overdose was of a combination product).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1-7). Administer supplemental oxygen.
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and noncardiogenic pulmonary edema (p 7) if they occur.

B. Specific drugs and antidotes

1. **Naloxone** (see p 469) is a specific opioid antagonist with no agonist properties of its own; large doses may be given safely.
 - a. Administer naloxone, 0.4-2 mg IV. As little as 0.2-0.4 mg is usually effective for heroin overdose. Repeat doses every 2-3 minutes if there is no response, up to a total dose of 10-20 mg if an opioid overdose is strongly suspected.
 - b. **Caution:** The duration of effect of naloxone (1-2 hours) is shorter than that of many opioids. Therefore, do not release the patient who has awakened after naloxone treatment until at least 3-4 hours have passed since the last dose of naloxone. In general, if naloxone was required to reverse opioid-induced coma, it is safer to admit the patient for at least 6-12 hours of observation.
2. **Nalmefene** (see p 469) is an opioid antagonist with a longer duration of effect (3-5 hours).
 - a. Nalmefene may be given in doses of 0.1-2 mg IV, with repeated doses up to 10-20 mg if an opioid overdose is strongly suspected.
 - b. **Caution:** While nalmefene's duration of effect is longer than that of naloxone, it is still much shorter than the duration of effect of methadone. If a methadone overdose is suspected, the patient should be observed for at least 8-12 hours after the last dose of nalmefene.
3. **Sodium bicarbonate** (see p 419) may be effective for QRS interval prolongation or hypotension associated with propoxyphene poisoning.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of the potential for developing lethargy and coma.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

- D. **Enhanced elimination.** Because of the very large volumes of distribution of the opioids and the availability of an effective antidotal treatment, there is no role for enhanced elimination procedures.

Gill JR, Graham SM: Ten years of "body packers" in New York City: 50 deaths. *J Forensic Sci* 2002;47(4):843–846. [PMID: 12136995] (Coroner's 10-year case series. Of 50 deaths, 42 were transporting opiates and 4 were transporting opiates and cocaine.)

Schneir AB et al: Massive OxyContin ingestion refractory to naloxone therapy. *Ann Emerg Med* 2002;40(4):425–428. [PMID: 12239500] (Case report of massive oxycodone overdose requiring mechanical ventilation for 3 days.)

► ORGANOPHOSPHORUS AND CARBAMATE INSECTICIDES

Michael A. Miller, MD

Organophosphorus compounds and carbamates, also known more generally as *cholinesterase inhibitors*, are widely used pesticides that may cause poisonings after accidental or suicidal exposure. Poisonings are particularly common in rural areas and third-world countries where more potent agents are widely available. Several **chemical warfare agents** (eg, GA [Tabun], GB [Sarin], GD [Soman], GF, and VX) are extremely potent cholinesterase inhibitors (see p 372 and Table II–57). Household insect sprays often contain low-potency cholinesterase inhibitors. (Many commercial products also contain solvents such as toluene or xylene that can themselves produce toxic effects in an overdose; see p 357).

I. Mechanism of toxicity

A. Organophosphorus (OP) compounds inhibit the enzyme acetylcholinesterase (AChE), allowing the accumulation of excessive acetylcholine at muscarinic receptors (cholinergic effector cells), at nicotinic receptors (skeletal neuromuscular junctions and autonomic ganglia), and in the central nervous system.

1. Permanent binding to the acetylcholinesterase enzyme ("aging") may occur after a variable delay unless antidotal treatment with an enzyme reactivator is given.
2. Reactivation of inhibited AChE occurs more quickly with dimethylated OPs compared with diethylated OPs. Oximes (see Pralidoxime, p 492) speed up this reactivation.
3. Aging occurs more quickly with dimethylated OPs compared with diethylated OPs. As a result, it may not be possible to reactivate AChE inhibited by dimethylated OPs after 12 h, while AChE inhibited by diethylated OPs may be reactivatable for several days. Antidotal treatment with an oxime may prolong the half-life of aging; early administration of oximes is therefore likely to be valuable.

B. Carbamates also inhibit acetylcholinesterase and produce similar clinical effects. However, reactivation occurs much more quickly than with OPs. Toxicity is therefore usually brief and self-limited and oximes are not required. **Aldicarb** is an important carbamate because it is relatively more potent and is translocated systemically by certain plants (eg, melons) and concentrated in their fruit. An acute outbreak of aldicarb poisoning occurred in California in 1985 after ingestion of watermelons that had been grown in a field previously sprayed with aldicarb. A similar outbreak after ingestion of contaminated cucumbers occurred in Dublin, Ireland, in 1992. The use of an imported rodenticide "Tres Pasitos" led to an epidemic of aldicarb poisoning in New York in 1994–1997.

C. Many of these agents can be absorbed by inhalation and ingestion and through the skin (with the exception of aldicarb, most carbamates are poorly absorbed across the skin compared with organophosphates). **Highly lipophilic organophosphates** (eg, disulfoton, fenthion, and others) are stored in fat tissue, which may lead to persistent toxicity lasting several days after exposure.

- II. Toxic dose.** There is a wide spectrum of relative potency of the organophosphorus and carbamate compounds (Table II–44). The severity and tempo of intoxication is also affected by the rate of exposure (acute versus chronic), the ongoing metabolic degradation and elimination of the agent, and for organophosphorus compounds, the rate of metabolism to their toxic “-oxon” derivatives. Some agents, including the highly toxic “nerve gases” developed for chemical warfare, are direct and powerful inhibitors of cholinesterase.
- III. Clinical presentation.** Signs and symptoms of acute organophosphate poisoning may occur within 1–2 hours of exposure but may also be delayed, especially

TABLE II–44. RELATIVE TOXICITIES OF ORGANOPHOSPHORUS AND CARBAMATE COMPOUNDS*

ORGANOPHOSPHATES		
Low Toxicity (LD ₅₀ > 1000 mg/kg)	Moderate Toxicity (LD ₅₀ 50–1000 mg/kg)	High Toxicity (LD ₅₀ < 50 mg/kg)
Bromophos	Acephate	Azinphos-methyl
Etrimfos	Bensulide	Bomyl
Iodofenphos (jodfenphos)	Chlorpyrifos	Carbophenothion
Malathion	Crotoxyphos	Chlorfenvinphos
Phoxim	Cyanophos	Chlormephos
Primiphos-methyl	Cythioate	Coumaphos
Propylthiopyrophosphate	DEF	Cyanofenphos
Temephos	Demeton-S-methyl	Demeton
Tetrachlorvinphos	Diazinon	Dialifor
	Dichlofenthion	Dicrotophos
	Dichlorvos (DDVP)	Disulfoton
	Dimethoate	EPN
	Edifenphos	Famphur
	EPBP	Fenamiphos
	Ethion	Fenophosphon
	Ethoprop	Fensulfothion
	Fenthion	Fonofos
	Fenitrothion	Isofenphos
	Formothion	Isofluorphate
	Heptenophos	Mephosfolan
	IBP (Kitacin)	Methamidophos
	Isoxathion	Methidathion
	Leptophos	Mevinphos
	Methyl trithion	Monocrotophos
	Naled	Parathion
	Oxydemeton-methyl	Phorate
	Oxydeprofos	Phosfolan
	Phencapton	Phosphamidon
	Phenthoate	Prothoate
	Phosalone	Schradan
	Phosmet	Sulfotep
	Pirimiphos-ethyl	Terbufos
	Profenofos	Tetraethylpyrophosphate
	Propetamphos	Triorthocresylphosphate
	Pyrazophos	
	Pyridaphenthion	
	Quinalphos	
	Sulprofos	
	Thiometon	
	Triazophos	
	Tribufos	
	Trichlorfon	

(continued)

TABLE II-44. RELATIVE TOXICITIES OF ORGANOPHOSPHORUS AND CARBAMATE COMPOUNDS^a (CONTINUED)

CARBAMATES		
Low Toxicity (LD ₅₀ > 200 mg/kg)	Moderate Toxicity (LD ₅₀ 50–200 mg/kg)	High Toxicity (LD ₅₀ < 50 mg/kg)
BPMC (Fenocarb)	Benfuracarb	Aldicarb
Carbaryl	Bufencarb	Aldoxycarb
Ethiofencarb	Carbosulfan	Aminocarb
Isoprocarb	Dioxacarb	Bendiocarb
MPMC (Meobal)	Pirimicarb	Carbofuran
MTMC (Metacrate)	Promecarb	Dimetilan
XMC (Cosban)	Propoxur	Formetanate
	Thiodicarb	Isolan
	Trimethacarb	Mecarbam
		Methiocarb
		Methomyl
		Mexacarbate
		Oxamyl

^aBased on oral LD₅₀ values in the rat. Note: The likelihood of serious toxicity depends not only on the dose of the pesticide but also on the route or exposure, circumstances of the exposure, and preexisting cholinesterase activity. Moreover, agents that are highly lipid soluble, such as fenthion and sulfoton, may cause prolonged intoxication.

after skin exposure or with intoxication by agents (eg, chlorpyrifos, malathion, many others) that must undergo metabolism to their active “-oxon” form. Sudden deterioration can occur in a patient with few initial symptoms. Clinical manifestations may be classified into muscarinic, nicotinic, and CNS effects. In addition, chemical pneumonitis (see p 219) may occur if a product containing a hydrocarbon solvent is aspirated into the lungs.

A. Muscarinic manifestations include vomiting, diarrhea, abdominal cramping, bronchospasm, miosis, bradycardia, and excessive salivation and sweating. Severe diaphoresis can actually lead to dehydration with systemic hypovolemia, resulting in shock.

B. Nicotinic effects include muscle fasciculations, tremor, and weakness. Death is usually caused by respiratory muscle paralysis. Blood pressure and pulse rate may be increased because of nicotinic effects or decreased because of muscarinic effects.

C. Central nervous system poisoning may cause agitation, seizures, and coma.

D. Intermediate syndrome. Patients may develop proximal muscle weakness over a few days even after resolution of the acute cholinergic crisis. This is often first noted as neck weakness, progressing to proximal limb weakness and cranial nerve palsies. Respiratory muscle weakness and respiratory arrest may occur abruptly. The intermediate syndrome is probably caused by prolonged overstimulation of the neuromuscular junction, and may be associated with inadequate oxime therapy. Atropine is not effective.

E. In addition to CNS sequelae, some cholinesterase inhibitors may cause a delayed, often permanent **peripheral neuropathy**.

IV. Diagnosis is based on the history of exposure and the presence of characteristic muscarinic, nicotinic, and CNS manifestations of acetylcholine excess. There may be a solvent odor, and some agents have a strong garlicky odor.

A. Specific levels

1. Organophosphorus compounds. Laboratory evidence of poisoning may be obtained by measuring decreases in the plasma pseudocholinesterase (PChE) and red blood cell acetylcholinesterase (AChE) activities. However, because of wide interindividual variability, significant depression of enzyme activity may occur but still fall within the “normal” range. It is most

helpful if the patient had a preexposure baseline measurement for comparison (eg, as part of a workplace health surveillance program).

- a. The AChE activity provides a more reliable measure of the toxic effect; a 25% or greater depression in activity from baseline generally indicates a true exposure effect.
 - b. PChE activity is a sensitive indicator of exposure but is not as specific as AChE activity (PChE may be depressed owing to genetic deficiency, medical illness, or chronic organophosphorus exposure). PChE activity usually recovers within weeks after exposure, whereas AChE recovery may take several months.
2. **Carbamate** poisoning produces reversible acetylcholinesterase inhibition, and spontaneous recovery of enzyme activity may occur within several hours, making these tests less useful.
3. Assay of blood, urine, gastric lavage fluid, and excrement for specific agents and their metabolites may also provide evidence of exposure, but these tests are not widely available.
- B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, arterial blood gases or oximetry, ECG monitoring, and chest x-ray (if pulmonary edema or aspiration of hydrocarbon solvent is suspected).

V. Treatment

- A. **Emergency and supportive measures.** **Caution:** Rescuers and health care providers must take measures to prevent direct contact with the skin or clothing of contaminated victims, because secondary contamination and serious illness may result, especially with potent pesticides and nerve agents (see Section IV, p 514.)
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Pay careful attention to respiratory muscle weakness; sudden respiratory arrest may occur. This is often preceded by increasing weakness of neck flexion muscles. If intubation is required, note the potential for interactions between neuromuscular blockers and cholinesterase inhibitors (see p 472). Administer supplemental oxygen.
 2. Treat hydrocarbon pneumonitis (see p 219), seizures (p 22), and coma (p 19) if they occur.
 3. Observe asymptomatic patients for at least 8–12 hours to rule out delayed-onset symptoms, especially after extensive skin exposure or ingestion of a highly fat-soluble agent.
- B. **Specific drugs and antidotes.** Specific treatment includes the antimuscarinic agent **atropine** and the enzyme reactivator **pralidoxime**.
1. Give **atropine**, 0.5–2 mg IV initially (see p 412), repeated frequently as needed. Large cumulative doses of atropine (up to 100 mg or more) may occasionally be required in severe cases. The most clinically important indication for continued atropine administration is persistent wheezing or bronchorrhea. **Note:** Atropine will reverse muscarinic but not nicotinic effects.
 2. **Pralidoxime** (2-PAM, Protopam; see p 492) is a specific antidote that acts to regenerate the enzyme activity at all affected sites. Other oximes include obidoxime and HI-6.
 - a. Pralidoxime should be given immediately to reverse muscular weakness and fasciculations: 1–2 g initial bolus dose (20–40 mg/kg in children) IV over 5–10 minutes, followed by a continuous infusion (see p 492). It is most effective if started early, before irreversible phosphorylation of the enzyme, but may still be effective if given later, particularly after exposure to highly lipid-soluble compounds. Although randomized clinical trials of oxime therapy have not yet been completed, we recommend that oximes should be given for 7 days or until 24 h after atropine is no longer required. This may be particularly beneficial for lipid-soluble OPs being released slowly into the blood from fat stores.
 - b. Pralidoxime is not generally recommended for carbamate intoxication, because in such cases the cholinesterase inhibition is spontaneously

reversible and short-lived. However, if the exact agent is not identified and the patient has significant toxicity, pralidoxime should be given empirically.

C. Decontamination (see p 46). **Note:** Rescuers must wear chemical-protective clothing and gloves when handling a grossly contaminated victim. If there is heavy liquid contamination with a solvent such as xylene or toluene, clothing removal and victim decontamination should be carried out outdoors or in a room with high-flow ventilation.

1. Skin. Remove all contaminated clothing and wash exposed areas with soap and water, including the hair and under the nails. Irrigate exposed eyes with copious tepid water or saline.

2. Ingestion (see p 48)

a. Prehospital. Administer activated charcoal, if available. Do **not** induce vomiting because of the risk of abrupt onset of toxicity.

b. Hospital. Administer activated charcoal (cathartics are not necessary if the patient already has diarrhea). Consider inserting a small flexible gastric tube to aspirate liquid gastric contents, if this procedure can be carried out safely and within 1–2 h of ingestion. (The inadvertent introduction of hydrocarbon solvents into the lungs through overly aggressive gastric lavage may kill the patient.)

D. Enhanced elimination. Dialysis and hemoperfusion are not generally indicated because of the large volume of distribution of organophosphates and the effectiveness of the specific therapy described above. Repeat-dose activated charcoal (see p 57) is theoretically applicable to **aldicarb** poisoning, because the agent undergoes significant enterohepatic recirculation.

► OXALIC ACID

Kent R. Olson, MD

Oxalic acid and oxalates are used as bleaches, metal cleaners, and rust removers and in chemical synthesis and leather tanning. Soluble and insoluble oxalate salts are found in several species of plants.

I. Mechanism of toxicity

A. Oxalic acid solutions are highly irritating and corrosive. Ingestion and absorption of oxalate cause acute hypocalcemia resulting from precipitation of the insoluble calcium oxalate salt. Calcium oxalate crystals may then deposit in the brain, heart, kidneys, and other sites, causing serious systemic damage.

B. Insoluble calcium oxalate salt found in dieffenbachia and similar plants is not absorbed but causes local mucous membrane irritation.

II. Toxic dose. Ingestion of 5–15 g of oxalic acid has caused death. The recommended workplace limit (ACGIH TLV-TWA) for oxalic acid vapor is 1 mg/m³ as an 8-hour time-weighted average. The level considered immediately dangerous to life or health (IDLH) is 500 mg/m³.

III. Clinical presentation. Toxicity may occur as a result of skin or eye contact, inhalation, or ingestion.

A. Acute skin or eye contact causes irritation and burning, which may lead to serious corrosive injury if the exposure and concentration are high.

B. Inhalation may cause sore throat, cough, and wheezing. Large exposures may lead to chemical pneumonitis or pulmonary edema.

- C. Ingestion** of soluble oxalates may result in weakness, tetany, convulsions, and cardiac arrest owing to profound hypocalcemia. The QT interval may be prolonged, and variable conduction defects may occur. Oxalate crystals may be found on urinalysis. Insoluble oxalate crystals are not absorbed but can cause irritation and swelling in the oropharynx and esophagus.
- IV. Diagnosis** is based on a history of exposure and evidence of local or systemic effects or oxalate crystalluria.
- A. Specific levels.** Serum oxalate levels are not available.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, calcium, ECG monitoring, and urinalysis.
- V. Treatment**
- A. Emergency and supportive measures**
1. Protect the airway (see p 1), which may become acutely swollen and obstructed after significant ingestion or inhalation. Administer supplemental oxygen, and assist ventilation if necessary (pp 1–7).
 2. Treat coma (see p 19), seizures (p 22), and arrhythmias (pp 10–15) if they occur.
 3. Monitor the ECG and vital signs for at least 6 hours after significant exposure, and admit symptomatic patients to an intensive care unit.
- B. Specific drugs and antidotes.** Administer 10% **calcium solution** (chloride or gluconate) to counteract symptomatic hypocalcemia (see p 424).
- C. Decontamination** (see p 46)
1. **Insoluble oxalates** in plants. Flush exposed areas. For ingestions, dilute with plain water; do not induce vomiting or give charcoal.
 2. **Oxalic acid or strong commercial oxalate solutions.** Immediately flush with copious water. Do **not** induce vomiting because of the risk of aggravating corrosive injury; instead, give water to dilute, and on arrival in the hospital perform gastric lavage.
 3. **Plants containing soluble oxalates.** Attempt to precipitate ingested oxalate in the stomach by administering calcium (calcium chloride or gluconate, 1–2 g; or calcium carbonate [Tums], several tablets) orally or via gastric tube. The effectiveness of activated charcoal is unknown. After a large recent ingestion, consider using ipecac to induce vomiting at home, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
- D. Enhanced elimination.** Maintain high-volume urine flow (3–5 mL/kg/h) to help prevent calcium oxalate precipitation in the tubules. Oxalate is removed by hemodialysis, but the indications for this treatment are not established.

Sanz P, Reig R: Clinical and pathological findings in fatal plant oxalosis. A review. *Am J Forensic Med Pathol* 1992;13(4):342–345. [PMID: 1288268] (Review.)

► PARAQUAT AND DIQUAT

Richard J. Geller, MD, MPH

Paraquat and diquat are dipyrpyridyl herbicides used for weed control and as preharvest (desiccant) defoliants. Paraquat has been used for large-scale control of illegal marijuana growing. Dipyrpyridyl product formulations differ by country. In the United States, paraquat has been available as a concentrated (29–44%) liquid. Diquat is found in aqueous concentrates containing 8–37.3% of the herbicide. Granular formulations containing a 2.5% mixture of paraquat and diquat salts are also available.

I. Mechanism of toxicity

- A. Paraquat and diquat** are strong cations in aqueous solution, and concentrated solutions (eg, >20%) may cause severe corrosive injury when ingested, injected, or applied to the skin, eyes, or mucous membranes. The dipyrpyridyl herbicides are extremely potent systemic toxins when absorbed and can

cause multiple system organ damage. Reaction of these dicationic compounds with NADPH produces highly reactive free radicals including superoxide anions, leading to tissue destruction through lipid peroxidation.

1. **Paraquat** is selectively taken up and concentrated by pulmonary alveolar cells, leading to cell necrosis followed by connective tissue proliferation and pulmonary fibrosis.
2. **Diquat** is not taken up by pulmonary alveolar cells and does not cause pulmonary fibrosis, but is associated with gastrointestinal fluid sequestration, renal failure, and cerebral and brainstem hemorrhagic infarctions.

B. Pharmacokinetics

1. **Absorption.** Paraquat and diquat are rapidly absorbed from the gastrointestinal tract, and peak serum levels are reached within 2 hours of ingestion. The presence of food may significantly reduce absorption. Although absorption is poor through intact skin, the dipyrindyl herbicides can be taken up through abraded skin or after prolonged contact with concentrated solutions. Fatalities usually result from ingestion, but have been reported after intramuscular injection, vaginal and percutaneous exposure, and rarely after inhalation.
2. **Distribution.** Paraquat has an apparent volume of distribution (V_d) of 1.2–1.6 L/kg. It is distributed most avidly to lung, kidney, liver, and muscle tissue; in the lungs, paraquat is actively taken up against a concentration gradient.
3. **Elimination.** Paraquat is eliminated renally, with more than 90% excreted unchanged within 12–24 hours if renal function is normal. Diquat is eliminated renally and via the gastrointestinal tract.

II. Toxic dose. Diquat is slightly less toxic than paraquat. However, this distinction may be of little comfort, as both compounds are extremely poisonous.

A. Paraquat. Ingestion of as little as 2–4 g, or 10–20 mL, of concentrated 20% paraquat solution has resulted in death. The estimated lethal dose of 20% paraquat is 10–20 mL for adults and 4–5 mL for children.

1. If food is present in the stomach, it may bind paraquat, preventing its absorption and reducing its toxicity.
2. Once applied to plants or soil, paraquat is rapidly bound and is not likely to be toxic. When burned, it is combusted and does not produce poisoning.

B. Diquat. The animal LD_{50} is approximately 400 mg/kg. The estimated lethal dose for adults is 30–60 mL of 20% diquat.

III. Clinical presentation

A. Paraquat. After ingestion of concentrated solutions, there is pain and swelling in the mouth and throat and oral ulcerations may be visible. Nausea, vomiting, and abdominal pain are common. The severity and tempo of illness depend on the dose. Ingestion of more than 40 mg/kg (about 14 mL of a 20% solution in an adult) leads to corrosive gastrointestinal injury, rapid onset of renal failure, myonecrosis, shock, and death within hours to a few days. Ingestion of 20–40 mg/kg causes a more indolent course evolving over several days, with most patients dying from pulmonary fibrosis after days to weeks. Patients with ingestions of less than 20 mg/kg usually recover fully.

B. Diquat causes similar initial symptoms, but does not cause pulmonary fibrosis. Severe gastroenteritis and gastrointestinal fluid sequestration may cause massive fluid and electrolyte loss contributing to renal failure. Agitation, seizures, and coma have been described. Cerebral and brainstem hemorrhagic infarctions may occur.

IV. Diagnosis is based on a history of ingestion and the presence of gastroenteritis and oral burns. The oral mucosal burns may have the appearance of a pseudomembrane on the soft palate, sometimes confused with diphtheria. Rapidly progressive pulmonary fibrosis suggests paraquat poisoning.

A. Specific levels. The prognosis may be correlated with specific serum levels, but these levels are not likely to be available in a time frame useful for emergency management. Assistance in obtaining and interpreting paraquat and di-

quat levels can be obtained through Syngenta ([800] 327-8633). Paraquat levels associated with a high likelihood of death are 2 mg/L at 4 hours, 0.9 mg/L at 6 hours, and 0.1 mg/L at 24 hours after ingestion.

- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, urinalysis, arterial blood gases or oximetry, and chest x-ray. Rapid rise of the creatinine (out of proportion to the BUN) has been seen.

V. Treatment

- A. Emergency and supportive measures.** Assistance in managing paraquat and diquat exposure can be obtained 24 hours a day by contacting the **Syngenta Agricultural Products Emergency Information Network ([800] 327-8633)**.

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat fluid and electrolyte imbalance caused by gastroenteritis with intravenous crystalloid solutions.
3. Avoid excessive oxygen administration in patients with **paraquat** poisoning, as this may aggravate lipid peroxidation reactions in the lungs. Treat significant hypoxemia with supplemental oxygen, but use only the lowest oxygen concentration necessary to achieve a pO_2 of about 60 mm.

- B. Specific drugs and antidotes.** There is no specific antidote.

- C. Decontamination** (see p 46)

1. **Skin and eyes.** Remove all contaminated clothing, and wash exposed skin with soap and water. Irrigate exposed eyes with copious saline or water.
2. **Ingestion** (see p 48). Immediate and aggressive gastrointestinal decontamination is probably the only treatment that may significantly affect outcome after paraquat or diquat ingestion.
 - a. **Prehospital.** Administer activated charcoal if available. Prompt ingestion of *any* food may afford some protection if charcoal is not immediately available. Do **not** administer ipecac.
 - b. **Hospital.** Immediately administer 100 g of activated charcoal and repeat the dose in 1–2 hours. Gastric lavage may be helpful if performed within an hour of the ingestion, but should be preceded by a dose of activated charcoal. Various clays, such as bentonite and fuller's earth, also adsorb paraquat and diquat but are probably no more effective than charcoal.

- D. Enhanced elimination** (see p 54). Although charcoal hemoperfusion has been advocated, and early animal studies and human case reports suggested benefits, no controlled study has demonstrated improved outcome, and the current consensus is that the procedure is not indicated. Hemodialysis and forced diuresis are not effective.

► PENTACHLOROPHENOL AND DINITROPHENOL

Delia A. Dempsey, MS, MD

Pentachlorophenol (Pencloro, Penta, PCP, others) is a chlorinated aromatic hydrocarbon used as a fungicide to preserve wood. It is not available over the counter in the United States. Formerly it had wide use as a multipurpose pesticide. It is an environmental contaminant being investigated as a hormone disrupter.

Dinitrophenols (Dinoseb, DNP, dinitrobutylphenol, and analogs) have been used as insecticides, herbicides, fungicides, and chemical intermediaries and in some explosives, dyes, and photographic chemicals. Dinitrophenol has also been taken orally for weight reduction. The use of dinitrophenol as a pesticide or as a weight-reducing agent is banned in the United States, although the chemical appears to be available over the Internet.

I. Mechanism of toxicity

- A. Pentachlorophenol and dinitrophenols** uncouple oxidative phosphorylation in the mitochondria. Substrates are metabolized but the energy produced is dissipated as heat instead of producing adenosine triphosphate (ATP). The basal metabolic rate increases, placing increased demands on the cardiorespiratory system. Excess lactic acid results from anaerobic glycolysis.
- B. Dinitrophenols** may oxidize hemoglobin to methemoglobin (see p 261).
- C. In animal studies**, pentachlorophenol is mutagenic, teratogenic, and carcinogenic. DNP is teratogenic and may be weakly carcinogenic.

II. Toxic dose. These agents are readily absorbed through the skin, lungs, and gastrointestinal tract.

- A. Inhalation.** The air level of pentachlorophenol considered immediately dangerous to life or health (IDLH) is 2.5 mg/m^3 . The ACGIH recommended workplace air exposure limit (TLV-TWA) is 0.5 mg/m^3 as an 8-hour time-weighted average.
- B. Skin.** This is the main route associated with accidental poisoning. An epidemic of intoxication occurred in a neonatal nursery after diapers were inadvertently washed in 23% sodium pentachlorophenate.
- C. Ingestion.** The minimum lethal oral dose of pentachlorophenol for humans is not known, but death occurred after ingestion of 2 g. Ingestion of 1–3 g of dinitrophenol is considered lethal.

III. Clinical presentation. The toxic manifestations of pentachlorophenol and dinitrophenol are nearly identical. Profuse sweating, fever, tachypnea, and tachycardia are universally reported in serious poisonings.

- A. Acute exposure** causes irritation of the skin, eyes, and upper respiratory tract. Systemic absorption may cause headache, vomiting, weakness, and lethargy. Profound sweating, hyperthermia, tachycardia, tachypnea, convulsions, and coma are associated with severe or fatal poisonings. Pulmonary edema may occur. Death is usually caused by cardiovascular collapse or hyperthermia. After death an extremely rapid onset of rigor mortis is frequently reported. Dinitrophenol may also induce methemoglobinemia, liver and kidney failure, and yellow-stained skin.
- B. Chronic exposure** may present in a similar manner and in addition may cause weight loss, gastrointestinal disturbances, fevers and night sweats, weakness, flu-like symptoms, contact dermatitis, and aplastic anemia (rare). Cataracts and glaucoma have been associated with DNP.

IV. Diagnosis is based on history of exposure and clinical findings, and should be suspected in patients with fever, metabolic acidosis, diaphoresis, and tachypnea.

- A. Specific levels.** Blood levels are not readily available or useful for emergency management.
- B. Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, CPK, liver transaminases, amylase, urine dipstick for occult blood (positive with hemolysis or rhabdomyolysis), arterial blood gases, methemoglobin level, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), or hyperthermia (p 21) if they occur. Dehydration from tachypnea, fever, and sweating is common and may require large-volume fluid replacement.
3. Monitor asymptomatic patients for at least 6 hours after exposure.

4. Do **not** use salicylates or anticholinergic agents, as these may worsen hyperthermia. Paralysis with neuromuscular blockers may not be helpful given the intracellular mechanism for hyperthermia. Barbiturates (see pp 485, 486) may be of some value.
- B. **Specific drugs and antidotes.** There is no specific antidote. Treat methemoglobinemia with methylene blue (see p 466).
- C. **Decontamination** (see p 46)
 1. **Inhalation.** Remove the victim from exposure and administer supplemental oxygen if available.
 2. **Skin and eyes.** Remove contaminated clothing and store in a plastic bag; wash exposed areas thoroughly with soap and copious water. Irrigate exposed eyes with copious saline or tepid water. Rescuers should wear appropriate protective clothing and respirators to avoid exposure.
 3. **Ingestion** (see p 48)
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of the risk of seizures.
 - b. **Hospital.** Place a gastric tube, immediately administer a dose of activated charcoal, and then perform gastric lavage. After lavage, administer activated charcoal. For small ingestions, charcoal may be given without gut emptying.
- D. **Enhanced elimination.** There is no evidence that enhanced elimination procedures are effective.

Macnab AJ, Fielden SJ: Successful treatment of dinitrophenol poisoning in a child. *Pediatr Emerg Care* 1998;14(2):136–138. [PMID: 9583397] (Case report with literature review.)

► PHENCYCLIDINE (PCP) AND KETAMINE

Gregory Cham, MD

Phencyclidine [PCP, 1-(1-phenylcyclohexyl)-piperidine] is a dissociative anesthetic agent with properties similar to those of ketamine. It was previously marketed for veterinary use, and it became popular as an inexpensive street drug in the late 1960s. PCP is commonly smoked, but may also be snorted, ingested, or injected, and it is frequently substituted for or added to other illicit psychoactive drugs such as THC (tetrahydrocannabinol or marijuana), mescaline, or LSD. PCP is known by a variety of street names, including “Peace pill,” “Angel dust,” “Hog,” “Goon,” “Animal tranquilizer,” and “Krystal.” Various chemical analogs of PCP have been synthesized, including PCC (1-piperidionocyclohexanecarbinol), PCE (1-phenyl-cyclohexylethylamine), PHP (phenylcyclohexylpyrrolidine), and TCP (1[1-cyclohexyl]piperidine).

Ketamine [2-(2-chlorophenyl)-2-(methylamino)cyclohexanone] shares many pharmacological and clinical characteristics with PCP. Street names for ketamine include “Jet,” “Kit-kat,” “Special K,” “Special LA Coke,” “Super C,” and “Vitamin K.”

I. Mechanism of toxicity

- A. PCP and ketamine are dissociative anesthetics that produce generalized loss of pain perception with little or no depression of airway reflexes or ventilation. Psychotropic effects are mediated through several mechanisms, including stimulation of sigma opioid receptors; inhibition of reuptake of dopamine, norepinephrine, and serotonin; and blocking of potassium conductance.
- B. **Pharmacokinetics.** PCP is rapidly absorbed by inhalation or ingestion. The volume of distribution (Vd) is about 6 L/kg. The duration of clinical effects after an overdose is highly variable and ranges from 11–14 hours in one report to 1–4 days in another. PCP is eliminated mainly by hepatic metabolism, although renal and gastric excretion account for a small fraction and are pH dependent. (See also Table II–59.) Ketamine is well absorbed after snorting, in-

gestion, rectal administration, or injection. Effects last 30 minutes to 2 hours depending on the route of administration. It is metabolized by the liver. Renal elimination is an important route of elimination for norketamine, the active metabolite of ketamine.

II. Toxic dose

- A. **PCP.** In tablet form the usual street dose is 1–6 mg, which results in hallucinations, euphoria, and disinhibition. Ingestion of 6–10 mg causes toxic psychosis and signs of sympathomimetic stimulation. Acute ingestion of 150–200 mg has resulted in death. Smoking PCP produces rapid onset of effects and thus may be an easier route for users to titrate to the desired level of intoxication.
- B. **Ketamine.** Usual therapeutic anesthetic doses are 1–5 mg/kg IV or 5–10 mg/kg IM. Recreational doses range from 10 to 250 mg nasally, 40 to 450 mg orally or rectally, and 10 to 100 mg IM. The higher recreational doses are purported to achieve a psychic state called “the K-hole.”

III. Clinical presentation.

Clinical effects may be seen within minutes of smoking PCP and can last 24 hours or longer depending on the dose.

- A. **Mild intoxication** causes lethargy, euphoria, hallucinations, and occasionally bizarre or violent behavior. Hypersalivation and lacrimation may occur. Patients may abruptly swing between quiet catatonia and loud or agitated behavior. Vertical and horizontal nystagmus are prominent with PCP intoxication.
- B. **Severe PCP intoxication** produces signs of adrenergic hyperactivity, including hypertension, rigidity, localized dystonic reactions, hyperthermia, tachycardia, diaphoresis, pulmonary edema, convulsions, and coma. The pupils are sometimes paradoxically small. **Death** may occur as a result of self-destructive behavior or as a complication of hyperthermia (eg, rhabdomyolysis, renal failure, coagulopathy, or brain damage).
- C. Chronic ketamine abuse may cause memory impairment.

IV. Diagnosis

is suggested by the presence of rapidly fluctuating behavior, vertical nystagmus, and signs of sympathomimetic excess.

A. Specific levels

1. Specific serum PCP levels are not readily available, nor do they correlate reliably with the degree of intoxication. Levels of 30–100 ng/mL have been associated with toxic psychosis.
2. Qualitative urine screening for PCP is widely available. PCP analogs may not be detected on routine screening, although they can cross-react in some immunologic assays (see Table I–33, p 43). Ketamine is not detected on routine screening.

- B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, CPK, and urinalysis dipstick for occult blood (positive with myoglobinuria).

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (p 19), seizures (p 22), hypertension (p 17), hyperthermia (p 21), and rhabdomyolysis (p 27) if they occur.
3. Agitated behavior (p 24) may respond to limiting sensory stimulation but may require sedation with haloperidol (see p 451), midazolam, or diazepam (see p 415). Do **not** use physostigmine.
4. Monitor temperature and other vital signs for a minimum of 6 hours, and admit all patients with hyperthermia or other evidence of significant intoxication.

- B. **Specific drugs and antidotes.** There is no specific antidote.

- C. **Decontamination.** No decontamination measures are necessary after snorting, smoking, or injecting PCP or ketamine. For ingestion (see p 48):

1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting.

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. **Enhanced elimination.** Because of its large volume of distribution, PCP is not effectively removed by dialysis, hemoperfusion, or other enhanced removal procedures.
 1. Repeat-dose activated charcoal has not been studied but might marginally increase elimination by adsorbing PCP partitioned into the acidic stomach fluid. Continuous nasogastric suction has also been proposed for removal of gastric-partitioned PCP.
 2. Although urinary acidification increases the urinary concentration of PCP, there is no evidence that this significantly enhances systemic elimination; it may be dangerous because urinary acidification can aggravate myoglobinuric renal failure.

Giannini AJ et al: Acute ketamine intoxication treated by haloperidol: a preliminary study. *Am J Ther* 2000;7(6):389–391. [PMID: 11304647] (A double-blind study showed significant reduction in symptoms in patients given 5 mg IM haloperidol compared with placebo.)

► PHENOL AND RELATED COMPOUNDS

Gary W. Everson, PharmD

Phenol (carbolic acid) was introduced into household use as a potent germicidal agent but has limited use today because less toxic compounds have replaced it. Now phenol is most commonly found in topical skin products (eg, Campho-phenique contains 4.7% phenol) and is also used cosmetically as a skin-peeling agent. **Hexachlorophene** is a chlorinated biphenol that was widely used as a topical antiseptic and preoperative scrub until its adverse neurologic effects were recognized. Other phenolic compounds include **creosote**, **creosol**, **cresol**, **cresylic acid**, **hydroquinone**, **eugenol**, and **phenylphenol** (bisphenol, the active ingredient in Lysol). **Pentachlorophenol** and **dinitrophenols** are discussed on p 298.

- I. **Mechanism of toxicity.** Phenol denatures protein, disrupts the cell wall, and produces coagulative necrosis. It may cause corrosive injury to the eyes, skin, and respiratory tract. Systemic absorption causes CNS stimulation. The mechanism of CNS intoxication is not known. Some phenolic compounds (eg, dinitrophenol and hydroquinone) may induce hemolysis and **methemoglobinemia** (see p 261).
- II. **Toxic dose.** The minimum toxic and lethal doses have not been well established. Phenol is well absorbed by inhalation, skin application, and ingestion.
 - A. **Inhalation.** The ACGIH-recommended workplace exposure limit (TLV-TWA) is 5 ppm (19 mg/m³) as an 8-hour time-weighted average. The level considered immediately dangerous to life or health (IDLH) is 250 ppm.
 - B. **Skin application.** Death has occurred in infants from repeated dermal applications of small doses (one infant died after a 2% solution of phenol was applied for 11 hours on the umbilicus under a closed bandage). Solutions of >5% are corrosive.
 - C. **Ingestion.** Deaths have occurred after adult ingestions of 1–32 g of phenol; however, survival after ingestion of 45–65 g has been reported. As little as 50–500 mg has been reported as fatal in infants.
 - D. **Pharmacokinetics.** Phenol is rapidly absorbed by all routes. Its elimination half-life is 0.5–4.5 hours.
- III. **Clinical presentation.** Toxicity may result from inhalation, skin or eye exposure, or ingestion.
 - A. **Inhalation.** Vapors of phenol may cause respiratory tract irritation and chemical pneumonia. Smoking of clove cigarettes (clove oil contains the phenol derivative eugenol) may cause severe tracheobronchitis.
 - B. **Skin and eyes.** Topical exposure to the skin may produce a deep white patch that turns red, then stains the skin brown. This lesion is often relatively pain-

less. Eye irritation and severe corneal damage may occur if concentrated liquids are spilled into the eye.

- C. Ingestion** usually causes vomiting and diarrhea, and diffuse corrosive gastrointestinal tract injury may occur. Systemic absorption may cause agitation, confusion, seizures, coma, hypotension, arrhythmias, and respiratory arrest.

IV. Diagnosis is based on a history of exposure, the presence of a characteristic odor, and painless white skin burns.

- A. Specific levels.** Normal urine phenol levels are less than 20 mg/L. Urine phenol levels may be elevated in workers exposed to benzene and after use of phenol-containing throat lozenges and mouthwashes.

- B. Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, and ECG. After hydroquinone exposure, obtain a methemoglobin level.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and arrhythmias (pp 10–15) if they occur.
3. If corrosive injury to the gastrointestinal tract is suspected, consult a gastroenterologist for possible endoscopy.

- B. Specific drugs and antidotes.** No specific antidote is available. If **methemoglobinemia** occurs, administer methylene blue (see p 466).

C. Decontamination (see p 46)

1. **Inhalation.** Remove victims from exposure and administer supplemental oxygen if available.
2. **Skin and eyes.** Remove contaminated clothing and wash exposed skin with soapy water or, if available, mineral oil, olive oil, or petroleum jelly. Immediately flush exposed eyes with copious tepid water or saline.
3. **Ingestion** (see p 48)
 - a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because phenol is corrosive and may cause seizures.
 - b. **Hospital.** Administer activated charcoal, orally or by gastric tube. Consider gastric lavage for large recent ingestions.

- D. Enhanced elimination.** Enhanced removal methods are generally not effective because of the large volume of distribution of these lipid-soluble compounds. Hexachlorophene is excreted in the bile, and repeat-dose activated charcoal (see p 57) may possibly be effective in increasing its clearance from the gut.

Wu ML et al: Concentrated cresol intoxication. *Vet Hum Toxicol* 1998;40(6):341–343. [PMID: 9830694] (A 44-year-old man developed esophageal burns, metabolic acidosis, and acute renal failure after ingestion of 300 mL of a 50% cresol-soap solution.)

► PHENYTOIN

James David Barry, MD

Phenytoin is used orally for the prevention of generalized (grand mal) and partial complex seizures. Intravenous phenytoin is used to treat status epilepticus and occasionally as an antiarrhythmic agent. Oral formulations include suspensions, capsules, and tablet preparations. The brand Dilantin Kapseals exhibits delayed absorption characteristics not usually shared by generic products.

- I. Mechanism of toxicity.** Toxicity may be caused by the phenytoin itself or by the propylene glycol diluent used in parenteral preparations. To make it available for intravenous use, phenytoin must be dissolved in 40% propylene glycol and 10% ethanol at pH 12.

- A. **Phenytoin** suppresses high-frequency neuronal firing, primarily by increasing the refractory period of voltage-dependent sodium channels. Toxic levels usually cause central nervous system depression.
 - B. The **propylene glycol** diluent in parenteral preparations may cause myocardial depression and cardiac arrest when infused rapidly ($> 40\text{--}50\text{ mg/min}$ [$0.5\text{--}1\text{ mg/kg/min}$]). The mechanism is not known. The injectable form of phenytoin also is highly alkaline and can cause tissue necrosis if it infiltrates. **Fosphenytoin**, a water-soluble prodrug, does not contain the propylene glycol diluent and does not cause these toxic effects.
 - C. **Pharmacokinetics.** Absorption may be slow and unpredictable. The time to peak plasma levels varies with the dosage. The volume of distribution (Vd) is about $0.5\text{--}0.8\text{ L/kg}$. Protein binding is about 90% at therapeutic levels. Hepatic elimination is saturable (zero-order kinetics) at levels near the therapeutic range, so the apparent "half-life" increases as levels rise (26 hours at 10 mg/L , 40 hours at 20 mg/L , and 60 hours at 40 mg/L). See also Table II-59 (p 381).
- II. **Toxic dose.** The minimum acute toxic oral overdose is approximately 20 mg/kg . Because phenytoin exhibits dose-dependent elimination kinetics, accidental intoxication can easily occur in patients on chronic therapy owing to drug interactions or slight dosage adjustments.
- III. **Clinical presentation.** Toxicity caused by phenytoin may be associated with acute oral overdose or chronic accidental overmedication. In acute oral overdose, absorption and peak effects may be delayed.
- A. **Mild to moderate intoxication** commonly causes nystagmus, ataxia, and dysarthria. Nausea, vomiting, diplopia, hyperglycemia, agitation, and irritability have also been reported.
 - B. **Severe intoxication** can cause stupor, coma, and respiratory arrest. Although seizures have been reported, seizures in a phenytoin-intoxicated patient should prompt a search for other causes (eg, anoxia, hyperthermia, or an overdose of another drug). Death from isolated oral phenytoin overdose is extremely rare.
 - C. **Rapid intravenous injection**, usually at rates exceeding 50 mg/min , can cause profound hypotension, bradycardia, and cardiac arrest. These effects are attributed to the propylene glycol diluent. Cardiac toxicity does not occur with oral overdose, or with fosphenytoin.
- IV. **Diagnosis** is based on a history of ingestion or is suspected in any epileptic patient with altered mental status or ataxia.
- A. **Specific levels.** Serum phenytoin concentrations are generally available in all hospital clinical laboratories. Obtain repeated blood samples because slow absorption may result in delayed peak levels. The therapeutic concentration range is $10\text{--}20\text{ mg/L}$.
 - 1. Above 20 mg/L , nystagmus is common. Above 30 mg/L , ataxia, slurred speech, and tremor are common. With levels higher than 40 mg/L , lethargy, confusion, and stupor ensue. Survival has been reported in three patients with levels above 100 mg/L .
 - 2. Because phenytoin is protein bound, patients with renal failure or hypoalbuminemia may experience toxicity at lower serum levels. Free (unbound) serum phenytoin levels are not routinely available.
 - B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, serum albumin, and ECG monitoring (during intravenous infusion).
- V. **Treatment**
- A. **Emergency and supportive measures**
 - 1. Maintain an open airway and assist ventilation if necessary (see pp 1-7). Administer supplemental oxygen.
 - 2. Treat stupor and coma (see p 16) if they occur. Protect the patient from self-injury caused by ataxia.
 - 3. If seizures occur, consider an alternative diagnosis and treat with other usual anticonvulsants (see p 22).

4. If hypotension occurs with intravenous phenytoin administration, immediately stop the infusion and administer intravenous fluids and pressors (see p 16) if necessary.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available.

2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary after isolated oral phenytoin overdose.

D. Enhanced elimination. Repeat-dose activated charcoal (see p 57) may enhance phenytoin elimination, but is not necessary and may increase the risk of aspiration pneumonitis in drowsy patients. There is no role for diuresis, dialysis, or hemoperfusion.

Chua HC et al: Paradoxical seizures in phenytoin toxicity. *Singapore Med J* 1999;40(4):276–277. [PMID: 10487084] (Case series of three patients with levels of 43.5, 46.5, and 38.3 mg/L with paradoxical seizures, which resolved with reduction of serum phenytoin levels.)

Chua HC et al: Elimination of phenytoin in toxic overdose. *Clin Neurol Neurosurg* 2000;102(1): 6–8. [PMID: 10717394] (In this prospective study of nine patients with initial levels of 34–57.5 mg/L, phenytoin concentrations fell in a linear fashion at a rate of 4.6–5.9 mg/L per day.)

► PHOSGENE

John Balmes, MD

Phosgene was originally manufactured as a war gas. It is now used in the manufacture of dyes, resins, and pesticides. It is also commonly produced when chlorinated compounds are burned, such as in a fire, or in the process of welding metal that has been cleaned with chlorinated solvents.

- I. Mechanism of toxicity.** Phosgene is an irritant. However, because it is poorly water soluble, in lower concentrations it does not cause immediate upper-airway or skin irritation. Thus, an exposed individual may inhale phosgene deeply into the lungs for prolonged periods, where it is slowly hydrolyzed to hydrochloric acid. This results in necrosis and inflammation of the small airways and alveoli, which may lead to noncardiogenic pulmonary edema.
- II. Toxic dose.** The ACGIH-recommended workplace exposure limit (TLV-TWA) is 0.1 ppm (0.4 mg/m³) as an 8-hour time-weighted average. The level considered immediately dangerous to life or health (IDLH) is 2 ppm. Exposure to 50 ppm may be rapidly fatal.
- III. Clinical presentation.** Exposure to moderate concentrations of phosgene causes mild cough and minimal mucous membrane irritation. After an asymptomatic interval of 30 minutes to 8 hours (depending on the duration and concentration of exposure), the victim develops dyspnea and hypoxemia. Pulmonary edema may be delayed up to 24 hours. Permanent pulmonary impairment may be a sequela of serious exposure.
- IV. Diagnosis** is based on a history of exposure and the clinical presentation. Many other toxic gases may cause delayed-onset pulmonary edema (see p 7).
 - A. Specific levels.** There are no specific blood or urine levels.
 - B. Other useful laboratory studies** include chest x-ray and arterial blood gases or oximetry.
- V. Treatment**
 - A. Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen, and treat noncardiogenic pulmonary edema (see p 7) if it occurs.
 2. Monitor the patient for at least 12–24 hours after exposure because of the potential for delayed-onset pulmonary edema.

- B. Specific drugs and antidotes.** There is no specific antidote.
- C. Decontamination.** Remove the victim from exposure and give supplemental oxygen if available. Rescuers should wear self-contained breathing apparatus.
- D. Enhanced elimination.** These procedures are not effective.

Borak J, Diller WF: Phosgene exposure: mechanisms of injury and treatment strategies. *J Occup Environ Med* 2001;43(2):110–119. [PMID: 11227628] (Review of pathophysiology and treatment of phosgene-induced pulmonary edema.)

► PHOSPHINE AND PHOSPHIDES

Summon Chomchai, MD, MPH

Phosphine is a colorless gas that is heavier than air. It is odorless in its pure form, but impurities give it a characteristic fishy or garlic-like odor. It has been used for fumigation, and it is a serious potential hazard in operations producing metal phosphides, where phosphine can be released in the chemical reaction of water and metal alloys. Workers at risk include metal refiners, acetylene workers, fire fighters, pest-control operators, and those in the semiconductor industry. **Magnesium phosphide** and **aluminum phosphide** are available in pellets or tablets and are used as fumigants and rodenticides. **Zinc phosphide** is a crystalline, dark gray powder mixed into food as rodent bait. Phosphides are a leading cause of fatal suicides and accidental ingestions in India and many developing countries.

- I. Mechanism of toxicity.** Phosphine is a highly toxic gas, especially to the lungs, brain, kidneys, heart, and liver. The pathophysiologic action of phosphine is not clearly understood, but may be related to inhibition of electron transport in mitochondria. Phosphides liberate phosphine gas upon contact with moisture, and this reaction is enhanced in the acidity of the stomach. Phosphine is then absorbed through the gastrointestinal and respiratory tracts.

II. Toxic dose

- A. Phosphine gas.** The ACGIH-recommended workplace exposure limit (TLV-TWA) is 0.3 ppm (0.42 mg/m³), much lower than the minimal detectable (fishy odor) concentration of 1–3 ppm. Hence, the odor threshold does not provide sufficient warning of dangerous concentrations. An air level of 50 ppm is considered immediately dangerous to life or health (IDLH). Chronic exposure to sublethal concentrations for extended periods may produce toxic symptoms.
- B. Phosphides.** Ingestion of as little as 500 mg **aluminum phosphide** has caused death in an adult. In a reported case series, survivors ingested about 1.5 g (range 1.5–18) while fatal cases had ingested an average of 2.3 g (range 1.5–36). The LD₅₀ for **zinc phosphide** in rats is 40 mg/kg; the lowest reported lethal dose in humans is 4 g. A 36-year-old man who ingested 6 mg/kg zinc phosphide and was treated with ipecac and activated charcoal remained asymptomatic.

- III. Clinical presentation.** Inhalation of phosphine gas is associated with cough, dyspnea, headache, dizziness, and vomiting. Phosphide ingestion may cause nausea, vomiting, diarrhea, hypotension unresponsive to pressors, and a rotten fish or garlicky odor. Adult respiratory distress syndrome (ARDS), acute renal failure, hepatitis, seizures, and coma may occur. Myocardial injury manifested by elevated cardiac enzymes, ST-T wave changes, global hypokinesia and various atrial and ventricular arrhythmias have been reported, as well as pericardial and pleural effusions, adrenal necrosis, and pancreatitis. Methemoglobinemia has also been reported. The onset of symptoms is usually rapid, although delayed onset of pulmonary edema has been described.

- IV. Diagnosis** is based on a history of exposure to the agent. **Caution:** Pulmonary edema may have a delayed onset, and initial respiratory symptoms may be mild or absent.

A. Specific levels. Body fluid phosphine levels are not clinically useful.

B. Other useful laboratory studies include BUN, creatinine, electrolytes, liver transaminases, arterial blood gases or oximetry, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen, and treat noncardiogenic pulmonary edema (p 7) if it occurs.
2. Treat seizures (see p 22) and hypotension (p 16) if they occur.
3. Patients with a history of significant phosphine inhalation or phosphide ingestion should be admitted and observed for 48–72 hours for delayed onset of pulmonary edema.
4. Intravenous **magnesium** has been used to treat cardiac arrhythmias otherwise unresponsive to treatment.
5. In severe poisoning adrenal function may be compromised and intravenous **hydrocortisone** should be considered, especially if hypotension does not respond to IV fluids and vasopressors.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination Caregivers are at a low risk for secondary contamination, but off-gassing of phosphine may occur if the patient vomits or if gastric lavage fluid is not isolated.

1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Administer activated charcoal, although studies have not determined its binding affinity for phosphides. Consider gastric lavage for large recent ingestion. Use of 3–5% sodium bicarbonate in the lavage has been proposed (to reduce stomach acid and resulting production of phosphine) but is not of proven benefit.

D. Enhanced elimination. Dialysis and hemoperfusion have not been shown to be useful in hastening elimination of phosphine.

Nocera A et al: Dangerous bodies: a case of fatal aluminium phosphide poisoning. *Med J Aust* 2000 Aug 7;173(3):133–135. [PMID: 10979378] (A fatal poisoning forced evacuation of the emergency department.)

Singh S et al: Aluminum phosphide ingestion—a clinico-pathologic study. *J Toxicol Clin Toxicol* 1996;34(6):703–706. [PMID: 8941200] (Review of clinical and pathological findings in 195 patients, including 115 who died.)

► PHOSPHORUS

Summon Chomchai, MD, MPH

There are two naturally occurring types of elemental phosphorus: red and yellow.

Red phosphorus is not absorbed and is essentially nontoxic. In contrast, **yellow phosphorus** (also called **white phosphorus**) is a highly toxic cellular poison. Yellow/white phosphorus is a colorless or yellow wax-like crystalline solid, with a garlic-like odor, and is almost insoluble in water. Although no longer a component of matches, yellow/white phosphorus is still used in the manufacture of fireworks and fertilizer and as a rodenticide.

I. Mechanism of toxicity

A. Phosphorus is highly corrosive and is also a general cellular poison. Cardiovascular collapse occurring after ingestion probably results not only from fluid loss owing to vomiting and diarrhea but also from direct toxicity on the heart and vascular tone.

- B. Yellow/white phosphorus spontaneously combusts in air at room temperature to yield phosphorus oxide, a highly irritating fume.

II. Toxic dose

- A. **Ingestion.** The fatal oral dose of yellow/white phosphorus is approximately 1 mg/kg. Deaths have been reported after ingestion of as little as 3 mg in a 2-year-old child.
- B. **Inhalation.** The recommended workplace limit (ACGIH TLV-TWA) for yellow or white phosphorus is 0.1 mg/m³ (0.02 ppm) as an 8-hour time-weighted average. The air level considered immediately dangerous to life or health (IDLH) is 5 mg/m³.

III. Clinical presentation

- A. **Acute inhalation** may cause conjunctivitis, mucous membrane irritation, cough, wheezing, chemical pneumonitis, and noncardiogenic pulmonary edema. **Chronic inhalation** of phosphorus (over at least 10 months) may result in mandibular necrosis ("phossy jaw").
- B. **Skin or eye contact** may cause severe dermal or ocular burns.
- C. **Acute ingestion** may cause gastrointestinal burns, severe vomiting and abdominal pain, and diarrhea with "smoking" stools. Systemic effects include headache, delirium, shock, seizures, coma, and arrhythmias (atrial fibrillation, QT prolongation, ventricular tachycardia, and fibrillation). Metabolic derangements, including hypocalcemia and hyperphosphatemia (or hypophosphatemia), may occur. Fulminant hepatic or renal failure may occur after 2–3 days.
- IV. **Diagnosis** is based on a history of exposure and the clinical presentation. Cutaneous burns, a garlic odor of the vomitus, and "smoking" or luminescent stools and vomitus caused by spontaneous combustion of elemental phosphorus suggest ingestion.
- A. **Specific levels.** Because serum phosphorus may be elevated, depressed, or normal, it is not a useful test for diagnosis or estimation of severity.
- B. **Other useful laboratory studies** include BUN, creatinine, liver transaminases, urinalysis, arterial blood gases or oximetry, and chest x-ray (after acute inhalation).

V. Treatment

A. Emergency and supportive measures

1. Observe the victim of inhalation closely for signs of upper-airway injury and perform endotracheal intubation and assist ventilation if necessary (see p 4). Administer supplemental oxygen. Treat bronchospasm (p 8) and pulmonary edema (p 7) if they occur.
2. Treat fluid losses from gastroenteritis with aggressive intravenous crystalloid fluid replacement.
3. Consider endoscopy if oral, esophageal, or gastric burns are suspected (see p 157).

B. Specific drugs and antidotes.

There is no specific antidote.

C. Decontamination (see p 46).

Rescuers should wear appropriate protective gear to prevent accidental skin or inhalation exposure. If solid phosphorus is brought into the emergency department, immediately cover it with water or wet sand.

1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen, if available.
2. **Skin and eyes.** Remove contaminated clothing and wash exposed areas with soap and water. Irrigate exposed eyes with copious tepid water or saline. Covering exposed areas may help prevent spontaneous combustion of yellow/white phosphorus.
3. **Ingestion (see p 48)**
 - a. **Prehospital.** Administer activated charcoal if available (although there is no evidence that it adsorbs phosphorus). Do **not** induce vomiting because of the potential for corrosive injury.

- b. Hospital.** Perform gastric lavage. Administer activated charcoal (although there is no evidence that it adsorbs phosphorus).
- D. Enhanced elimination.** There is no effective method of enhanced elimination.

Fernandez OU, Canizares LL: Acute hepatotoxicity from ingestion of yellow phosphorus-containing fireworks. *J Clin Gastroenterol* 1995;21(2):139–142. [PMID: 8583080] (Review of 15 cases of ingestion, of which 13 had varying degrees of hepatic injury and 4 died with fulminant liver failure.)

► PLANTS

Judith A. Alsop, PharmD

Ingestion of plants and berries by children is one of the top five reasons for calls to poison control centers. Decorative plants are found in many homes, and landscaped yards provide access to a variety of attractive and potentially toxic plants. Fortunately, serious poisoning from plants is rare in children because the quantity of plant material required to cause serious poisoning is greater than what the small child ingests. Serious toxicity or death from plant ingestion is usually a result of intentional abuse (eg, jimson weed), misuse (eg, various teas steeped from plants), or suicide attempts (eg, oleander).

- I. Mechanism of toxicity.** Plants can be categorized by their potential toxicity. Table II–45 describes the effects of various plant toxins. Table II–46 is an alphabetical list of potentially toxic plants and herbs.
- A. Group 1** plants contain systemically active poisons that may cause serious poisoning.
- B. Group 2a** plants contain insoluble calcium oxalate crystals that may cause burning pain and swelling of mucous membranes. Many houseplants are commonly found in this category.
- C. Group 2b** plants contain soluble oxalate salts (sodium or potassium) that can produce acute hypocalcemia, renal injury, and other organ damage secondary to precipitation of calcium oxalate crystals in various organs (see p 295). Mucous membrane irritation is rare, allowing patients to ingest sufficient quantities to cause systemic toxicity. Gastroenteritis may also occur.
- D. Group 3** plants contain various toxins that generally produce mild to moderate gastrointestinal irritation after ingestion, or dermatitis after skin contact.
- II. Toxic dose.** The amount of toxin ingested is usually unknown. Concentrations of the toxic agent may vary depending on the plant part, the season, and soil conditions. In general, childhood ingestions of a single leaf or a few petals, even of group 1 plants, results in little or no toxicity because of the small amount of the toxin absorbed. Steeping the plant in hot water (eg, an “herbal” tea) may allow very large amounts of toxin to be absorbed.
- III. Clinical presentation** depends upon the active toxic agent (see Table II–45), although even nontoxic plants can cause coughing, choking, and gagging if a large piece is swallowed.
- A. Group 1.** In most cases, vomiting, abdominal pain, and diarrhea occur within 60–90 minutes of a significant ingestion, but systemic symptoms may be delayed a few hours while toxins are activated in the gut (eg, cyanogenic glycosides) or distributed to tissues (eg, cardiac glycosides). With some toxins, (eg, ricin), severe gastroenteritis may result in massive fluid and electrolyte loss and gastrointestinal sloughing.
- B. Group 2a.** Insoluble calcium oxalate crystals cause immediate oral burning, pain, and stinging upon contact with mucous membranes. Swelling of the lips, tongue, and pharynx may occur. In rare cases, glottic edema may result in airway obstruction. Symptoms usually resolve within a few hours.

TABLE II-45. TOXIC EFFECTS OF PLANTS

Toxin	Clinical Effects
Aconitum	Tingling in digits followed by paresthesias, feeling of intense cold, gastroenteritis, skeletal muscle paralysis, ventricular arrhythmias, respiratory paralysis, death.
Aesculin	Single seed can cause gastroenteritis. Larger amounts can cause ataxia, gastroenteritis, CNS depression, and paralysis.
Anthraquinone	Severe diarrhea with GI bleeding, renal damage, dyspnea, and seizures.
Chinaberry	Tetranortriterpene neurotoxin: gastroenteritis, lethargy, coma, respiratory failure, seizures, paralysis.
Coniine	Salivation, vomiting, seizures followed by CNS depression and respiratory depression, rhabdomyolysis, renal failure, muscle paralysis, rapid death secondary to respiratory paralysis.
Cyanogenic glycosides	Dyspnea, cyanosis, weakness, seizures, coma, cardiovascular collapse. Symptoms may be delayed for 3-4 hours or more as glycoside is hydrolyzed to cyanide in the gut.
Cytisine	Vomiting, hypotension, tachycardia, paralysis, seizures, respiratory depression.
Euphorbiaceae	Oral irritation, gastroenteritis. Erythema, edema, followed by vesicle and blister formation. Eye exposure may result in corneal ulceration, iritis, conjunctivitis, and temporary blindness. Systemic symptoms: seizures, coma, and death.
Gelsemium indole-alkaloids	Headache, sweating, muscular weakness or rigidity, seizures, dyspnea, bradycardia, respiratory arrest.
Grayanotoxin	Burning, numbness, tingling of mouth, vomiting, hypotension, bradycardia, coma, seizures.
Hydroquinone	Vomiting, jaundice, dizziness, headache, delirium, pallor, anoxia, seizures, respiratory failure, cyanosis, cardiovascular collapse. Allergic contact dermatitis.
Lantadene	Anticholinergic effects with gastroenteritis, respiratory distress, ataxia, coma, depressed deep tendon reflexes, weakness, cyanosis, death.
Lobeline	Vomiting, bradycardia, hypertension, tachypnea, tremors, seizures, paralysis.
Nicotine alkaloids	Salivation, gastroenteritis, agitation followed by seizures and coma. Hypertension, tachycardia, tachypnea followed by hypotension, bradycardia, and bradypnea.
Protoanemonin	Acrid taste, burning in mouth and throat, oral ulceration, gastroenteritis, hematemesis.
Pyrrolizidine alkaloids	Gastroenteritis, hepatic veno-occlusive disease.
Quinolizidine	Vomiting, hypotension, tachycardia, seizures, paralysis, respiratory depression.
Sanguinaria	Gastroenteritis, CNS depression, ataxia, dyspnea, respiratory paralysis.
Saponin	Gastroenteritis, dermatitis, mydriasis, hyperthermia, ataxia, muscle weakness, dyspnea, coma.
Solanine	Salivation, gastroenteritis, coma, hypotension, bradycardia, cramping, paresthesias.
Tannin	Abdominal pain, extreme thirst, frequent urination, bloody diarrhea, rapid but weak pulse. Liver and kidney damage may occur several weeks later.
Toxalbumin	Severe gastroenteritis, sloughing of the GI tract followed by toxicity to the liver, CNS, kidney, and adrenals.
Veratum alkaloids	Gastroenteritis, bradycardia, syncope, paresthesias, hypotension.

TABLE II-46. POISONOUS PLANTS

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Acacia, black	<i>Robinia pseudoacacia</i>	1	Toxalbumin
Aconite	<i>Aconitum</i> spp	1	Nausea, vomiting, arrhythmias, shock
Acorn	<i>Quercus</i> spp	3	Tannin; dermatitis
Agapanthus	<i>Agapanthus</i> spp	3	Dermatitis
Akee	<i>Blighia sapida</i>	1	Hypoglycemia and hepatotoxicity
Alder, American	<i>Alnus crispus</i>	3	Dermatitis
Alder buckthorn	<i>Rhamnus frangula</i>	1	Antraquinone
Almond, bitter	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Aloe vera	<i>Aloe vera</i>	3	GI upset; skin irritant
Amaryllis	<i>Hippeastrum equestre</i>	3	GI upset
American bittersweet	<i>Celastrus scandens</i>	3	GI upset
American ivy	<i>Parthenocissus</i> spp	2b	Soluble oxalates
Angel's trumpet	<i>Brugmansia arborea</i> , <i>Datura</i> spp	1, 3	Anticholinergic alkaloids (see p 84)
Anthurium	<i>Anthurium</i> spp	2a	Calcium oxalate crystals
Apple (chewed seeds)	<i>Malus domestica</i>	1	Cyanogenic glycosides (see p 177)
Apricot (chewed pits)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Arrowhead vine	<i>Syngonium podophyllum</i>	2a	Calcium oxalate crystals
Arum	<i>Arum</i> spp	2a	Calcium oxalate crystals
Ash tree	<i>Fraxinus</i> spp	3	Dermatitis
Aspen tree	<i>Populus tremuloides</i>	3	Dermatitis
Autumn crocus	<i>Colchicum autumnale</i>	1	Colchicine (see p 173)
Avocado (leaves and seeds)	<i>Avocado</i>	1	Unknown toxin causing hepatitis, myocarditis in animals
Azalea	<i>Rhododendron</i> genus	1	Grayanotoxin
Bahia	<i>Bahia oppositifolia</i>	1	Cyanogenic glycosides (see p 177)
Baneberry	<i>Actaea</i> spp	1, 3	Irritant oil protoanemonin: severe gastroenteritis
Barbados nut; purging nut	<i>Jatropha</i> spp	1	Toxalbumin, Euphorbiaceae
Barberry	<i>Berberis</i> spp	3	GI upset
Beech, European	<i>Fagus sylvatica</i>	3	Saponins
Beech, Japanese	<i>Fagus crenata</i>	1	Saponins
Begonia	<i>Begonia rex</i>	2a	Calcium oxalate crystals
Belladonna	<i>Atropa belladonna</i>	1	Atropine (see p 84)
Bellyache bush	<i>Jatropha</i> spp	1	Euphorbiaceae
Be-still tree	<i>Thevetia peruviana</i>	1	Cardiac glycosides (see p 177)
Birch (bark, leaves)	<i>Betula</i> spp	1, 3	Methyl salicylate (see p 331), irritant oils causing GI upset
Bird of paradise	<i>Poinciana gillesii</i>	3	GI upset
Black cohosh	<i>Cimicifuga</i> spp	3	GI upset
Black-eyed Susan	<i>Rudbeckia hirta</i>	3	Dermatitis
Black henbane	<i>Hyoscyamus niger</i>	1	Anticholinergic alkaloids (see p 84)
Black lily	<i>Dracunculus vulgaris</i>	2a	Calcium oxalate crystals
Black locust	<i>Robinia pseudoacacia</i>	1	Toxalbumin
Black nightshade	<i>Hyoscyamus</i> spp	1	Solanine
Black snakeroot	<i>Cimicifuga racemosa</i>	3	GI upset
Black snakeroot	<i>Zigadenus</i> spp	1	Veratrum alkaloids
Bleeding heart	<i>Dicentra</i>	3	Dermatitis
Bloodroot	<i>Sanguinaria canadensis</i>	3	Sanguinaria
Blue cohosh	<i>Caulophyllum thalictroides</i>	1, 3	Cytisine; dermatitis
Boston ivy	<i>Parthenocissus</i> spp	2b	Soluble oxalates
Bougainvillea	<i>Bougainvillea glabra</i>	3	Dermatitis
Box elder	<i>Acer negundo</i>	3	Dermatitis
Boxwood; box plant	<i>Buxus</i> spp	3	GI upset, dermatitis
Bracken fern	<i>Pteridium aquilinum</i>	1	Potential carcinogen
Bradford pear	<i>Pyrus calleryana</i>	3	Dermatitis
Broom	<i>Cytisus</i> spp	1, 3	Cytisine; dermatitis
Buckeye	<i>Aesculus</i> spp	1, 3	Aesculin
Buckthorn	<i>Karwinskia humboltiana</i>	1	Chronic ingestion may cause ascending paralysis

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Buckthorn	<i>Rhamnus</i> spp	3	Anthraquinone
Bunchberry	<i>Cornus canadensis</i>	3	Dermatitis
Burdock root	<i>Arctium minus</i>	1, 3	Anticholinergic alkaloids (see p 84)
Burning bush	<i>Dictamnus albus</i>	3	Dermatitis
Burning bush	<i>Euonymus</i> spp	3	GI upset
Burning bush	<i>Kochia</i> spp	2a, 2b, 3	Soluble and insoluble oxalates, dermatitis
Buttercups	<i>Ranunculus</i> spp	3	Irritant oil protoanemonin
Cactus (thorn)	<i>Cactus</i>	3	Dermatitis, cellulitis, (abscess may result)
Caladium	<i>Caladium</i> spp; <i>Xanthosoma</i> spp	2a	Calcium oxalate crystal
California geranium	<i>Senecio</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
California poppy	<i>Eschscholzia californica</i>	3	Potentially mildly narcotic; Sanguinaria
California privet	<i>Ligustrum</i> spp	3	GI upset
Calla lily	<i>Zantedeschia</i> spp	2a	Calcium oxalate crystals
Cannabis	<i>Cannabis sativa</i>	1	Mild hallucinogen (see Marijuana, p 252)
Caraway	<i>Carum carvi</i>	3	Dermatitis
Cardinal flower	<i>Lobelia</i> spp	1	Lobeline: nicotinellike alkaloid (see p 277)
Carnation	<i>Dianthus caryophyllus</i>	3	Dermatitis
Carolina allspice	<i>Calycanthus</i> spp	1	Strychnine-like alkaloid (see p 348)
Cascara	<i>Rhamnus</i> spp	3	Anthraquinone cathartic
Cassava	<i>Manihot esculenta</i>	1	Cyanogenic glycosides (see p 177); Euphorbiaceae
Castor bean	<i>Ricinus communis</i>	1	Toxalbumin (ricin)
Catnip	<i>Nepeta cataria</i>	1, 3	Mild hallucinogen
Cedar	<i>Thuja</i> spp	3	Dermatitis
Century plant	<i>Agave americana</i>	3	Thorns can cause cellulitis
Chamomile	<i>Chamomilla recucita</i>	3	GI upset, dermatitis
Cherry (chewed pits)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Chili pepper	<i>Capsicum</i> spp	3	Irritant to skin, eyes, mucous membranes
Chinaberry	<i>Melia azedarach</i>	1, 3	Chinaberry: severe GI upset, seizures
Chokecherry	<i>Prunus virginiana</i>	1	Cyanogenic glycosides (see p 177)
Christmas rose	<i>Helleborus niger</i>	1, 3	Protoanemonin
Chrysanthemum; mum	<i>Chrysanthemum</i> spp	3	Dermatitis
Clematis	<i>Clematis</i> spp	3	Protoanemonin
Coffeeberry	<i>Rhamnus</i> spp	3	Anthraquinone cathartic
Cola nut	<i>Cola nitida</i>	1	Caffeine (see p 142)
Comfrey	<i>Symphytum officinale</i>	1, 3	Irritant tannin and hepatotoxic pyrrolizidine alkaloids
Conquerer root	<i>Exogonium purga</i>	3	GI upset
Coral bean	<i>Erythrina</i> spp	1	Cyanogenic glycosides (see p 177)
Coral bean	<i>Sophora secundiflora</i>	1	Cytisine: similar to nicotine (see p 277)
Coral berry	<i>Symphoricarpos</i> spp	3	Protoanemonin
Coriaria	<i>Coriaria myrtifolia</i>	1	Contains convulsant agent
Cotoneaster	<i>Cotoneaster</i>	1, 3	Cyanogenic glycosides (see p 177)
Cottonwood	<i>Populus deltoides</i>	3	Dermatitis
Coyotillo	<i>Karwinskia humboldtiana</i>	1	Chronic ingestion may cause ascending paralysis
Creeping charlie	<i>Glechoma hederacea</i>	3	GI upset
Crocus, wild or prairie	<i>Anemone</i> spp	3	Protoanemonin
Croton	<i>Codiaeum</i> spp	3	GI upset, dermatitis
Crowfoot	<i>Ranunculus repens</i>	1	Protoanemonin
Crown of thorns	<i>Euphorbia</i> spp	1, 3	Euphorbiaceae
Cyclamen	<i>Cyclamen</i>	3	GI upset
Daffodil (bulb)	<i>Narcissus</i> spp	2a, 3	Calcium oxalate crystals; GI upset
Daisy	<i>Chrysanthemum</i> spp	3	GI upset, dermatitis
Daisy, butter	<i>Ranunculus repens</i>	1	Protoanemonin

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Daisy, seaside	<i>Erigeron karvinskianus</i>	3	Dermatitis
Daphne	<i>Daphne</i> spp	1, 3	GI upset, dermatitis. Bark contains coumarin glycosides (see p 378)
Datura	<i>Datura</i> spp	1	Anticholinergic alkaloids (see p 84)
Deadly nightshade	<i>Atropa belladonna</i>	1	Atropine (see p 84)
Deadly nightshade	<i>Solanum</i> spp	1	Solanine
Death camas	<i>Zigadenus</i> spp	1	Veratrum alkaloids
Devils ivy	<i>Scindapsus aureus</i> , <i>Epipremnum aureum</i>	2a	Calcium oxalate crystals
Dieffenbachia	<i>Dieffenbachia</i> spp	2a	Calcium oxalate crystals
Dogbane	<i>Apocynum</i> spp	1	Cardiac glycosides (see p 177)
Dogwood, bloodtwig	<i>Cornus sanguinea</i>	3	Dermatitis
Dolls-eyes	<i>Actaea</i> spp	3	Irritant oil protoanemonin: severe gastroenteritis
Dragon root	<i>Arisaema</i> spp	2a	Calcium oxalate crystals
Dumbcane	<i>Dieffenbachia</i> spp	2a	Calcium oxalate crystals
Dusty miller	<i>Senecio</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
Eggplant (green parts)	<i>Solanum melongena</i>	1	Solanine
Elderberry	<i>Sambucus</i>	1	Unripe berries contain cyanogenic glycosides (see p 177)
Elephant's ear; taro	<i>Alacasia</i> spp; <i>Colocasia</i> spp; <i>Philodendron</i> spp	2a	Calcium oxalate crystals
Elm, Chinese	<i>Ulmus parvifolia</i>	3	Dermatitis
English ivy; heart ivy	<i>Hedera helix</i>	3	Saponins; dermatitis
English laurel	<i>Prunus laurocerasus</i>	1	Cyanogenic glycosides (see p 177)
Eucalyptus	<i>Eucalyptus</i>	3	GI upset
False hellebore	<i>Veratrum</i> spp	1, 3	Veratrum alkaloids
False parsley	<i>Cicuta maculata</i>	1	Water hemlock: cicutoxin causes seizures.
False parsley	<i>Aethusa cynapium</i>	1	Poison hemlock: coniine (similar to nicotine, see p 277)
Fava bean	<i>Vicia faba</i>	1	Hemolytic anemia in G6PD-deficient persons
Ficus (sap)	<i>Ficus benjamina</i>	3	Dermatitis
Firethorn	<i>Pyracantha</i>	3	GI upset
Flag	<i>Iris</i> spp	3	GI upset, dermatitis
Fleabane	<i>Erigeron</i> spp	3	Dermatitis
Fool's parsley	<i>Conium maculatum</i>	1	Coniine: nicotinellike alkaloid (see p 277)
Four o'clock	<i>Mirabilis jalapa</i>	3	Seeds have hallucinogenic effects
Foxglove	<i>Digitalis purpurea</i>	1	Cardiac glycosides (see p 177)
Garden sorrel	<i>Rumex</i> spp	2b	Soluble oxalates
Geranium	<i>Pelargonium</i> spp	3	Dermatitis
Geranium, California	<i>Senecio</i> spp	3	Hepatotoxic pyrrolizidine alkaloids
Ginkgo	<i>Ginkgo biloba</i>	1, 3	Dermatitis; chronic: increased bleeding time
Glacier ivy	<i>Hedera glacier</i>	3	Saponins
Glory pea	<i>Sesbania</i> spp	3	Saponins
Goldenrod; rayless	<i>Haplopappus heterophyllus</i>	1	CNS depression
Golden chain	<i>Laburnum anagyroides</i>	1	Cytisine
Golden seal	<i>Hydrastis</i> spp	1, 3	GI upset; possible systemic toxicity
Gordoloba	<i>Achillea millefolium</i>	3	GI upset, dermatitis
Gordolobo	<i>Senecio</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
Gotu kola	<i>Hydrocotyle asiatica</i>	1, 3	CNS depression, dermatitis
Grindelia	<i>Grindelia</i> spp	1	Balsamic resin: renal, cardiac toxicity
Groundsel	<i>Senecio</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
Guaiaic	<i>Guaicum officinale</i>	3	GI upset

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Harmaline	<i>Banisteriopsis</i> spp	1	Harmaline: hallucinogen (see p 247)
Harmel; Syrian rue	<i>Peganum harmala</i>	1	Harmaline: hallucinogen (see p 247)
Hawaiian woodrose	<i>Merremia tuberosa</i>	1	Hallucinogen
Hawaiian baby woodrose	<i>Argyrea nervosa</i>	1	Hallucinogen
Heart leaf philodendron	<i>Philodendron</i> spp	2a	Calcium oxalate crystals
Heath	<i>Ericaceae</i> family	1, 3	Grayanotoxin
Heliotrope	<i>Heliotropium</i> spp	1	Pyrrrolizidine alkaloids: hepatotoxicity
Hemlock (poison hemlock)	<i>Conium maculatum</i>	1	Coniine: nicotinellike alkaloid (see p 277)
Hemlock (water hemlock)	<i>Cicuta maculata</i>	1	Cicutoxin: seizures
Henbane; black henbane	<i>Hyoscyamus</i> spp	1	Anticholinergic alkaloids (see p 84)
Holly (berry)	<i>Ilex aquifolium</i>	3	GI upset
Honeysuckle	<i>Caprifoliaceae</i> family	3	GI upset
Hops, European	<i>Humulus lupulus</i>	3	Dermatitis
Hops, wild	<i>Bryonia</i> spp	3	GI upset, dermatitis
Horse chestnut	<i>Aesculus</i> spp	1, 3	Aesculin
Hyacinth	<i>Hyacinthus</i>	3	GI upset, dermatitis
Hydrangea	<i>Hydrangea</i> spp	1, 3	Cyanogenic glycosides (see p 177)
Indian currant	<i>Symphoricarpos</i> spp	3	GI upset
Indian tobacco	<i>Lobelia</i> spp	1	Lobeline: nicotinellike alkaloid (see p 277)
Inkberry	<i>Ilex glabra</i>	3	GI upset
Inkberry	<i>Phytolacca americana</i>	3	Saponin
Iris	<i>Iris</i>	3	GI upset, dermatitis
Ivy	<i>Hedera</i> spp	3	GI upset, dermatitis
Ivy bush	<i>Kalmia</i> spp	1	Grayanotoxin
Jack-in-the-pulpit	<i>Arisaema</i> spp	2a	Calcium oxalate crystals
Jaggery palm	<i>Caryota urens</i>	2a	Calcium oxalate crystals
Jalap root	<i>Exogonium purga</i>	3	GI upset
Jasmine, Carolina	<i>Gelsemium sempervirens</i>	1	Gelsemium
Jequirity bean	<i>Abrus precatorius</i>	1	Toxalbumin (abrin): severe fatal gastroenteritis reported
Jerusalem cherry	<i>Solanum pseudocapsicum</i>	1, 3	Unripe berry contains solanine and anticholinergic alkaloids (see p 84)
Jessamine, Carolina or Yellow	<i>Gelsemium sempervirens</i>	1	Gelsemium
Jessamine, day or night	<i>Cestrum</i> spp	1, 3	Solanine and anticholinergic alkaloids (see p 84)
Jessamine, poet's	<i>Jasminum officinale</i>	3	Dermatitis
Jetberry bush, Jetbead	<i>Rhodotypos scandens</i>	1	Cyanogenic glycosides (see p 177)
Jimmyweed	<i>Haplopappus heterophyllus</i>	1	High alcohol tremetol: CNS depression
Jimsonweed	<i>Brugmansia arborea</i> , <i>Datura stramonium</i>	1	Anticholinergic alkaloids (see p 84)
Juniper	<i>Juniperus macropoda</i>	1, 3	GI upset, dermatitis; chronic: renal toxicity
Kava-kava	<i>Piper methysticum</i>	1	Acute: sedation, ataxia. Chronic: dermatitis and hepatotoxicity
Kentucky coffee tree	<i>Gymnocladus dioica</i>	1	Cytisine: similar to nicotine (see p 277)
Khat; chat	<i>Catha edulis</i>	1	Mild hallucinogen and stimulant
Ladyslipper	<i>Cypripedium</i> spp	3	Dermatitis
Lady's slipper	<i>Pedilanthus tithymaloides</i>	1	Euphorbiaceae
Lantana	<i>Lantana camara</i>	1	Lantadene
Larkspur	<i>Delphinium</i>	1	Aconitum-like
Laurel	<i>Laurus nobilis</i>	3	Dermatitis
Licorice root	<i>Glycyrrhiza lepidota</i>	1, 3	Hypokalemia after chronic use
Licorice, wild	<i>Abrus precatorius</i>	1	Toxalbumin
Lily of the Nile	<i>Agapanthus</i>	3	GI upset
Lily-of-the-valley	<i>Convallaria majalis</i>	1	Cardiac glycosides (see p 155)
Lily-of-the-valley bush	<i>Pieris japonica</i>	1	Grayanotoxin
Lobelia	<i>Lobelia berlandieri</i>	1	Lobeline

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Locoweed	<i>Datura stramonium</i>	1	Anticholinergic alkaloids (see p 84)
Locoweed	<i>Cannabis sativa</i>	1	Mild hallucinogen (see p 252)
Lupine	<i>Lupinus</i> spp	1	Quinolizidine
Mandrake root	<i>Mandragora officinarum</i>	1	Anticholinergic alkaloids (see p 84)
Mandrake	<i>Podophyllum peltatum</i>	1, 3	Oil is keratolytic, irritant; hypotension, seizures reported after ingestion of resin
Marble queen	<i>Scindapsus aureus</i>	2a	Calcium oxalate crystals
Marijuana	<i>Cannabis sativa</i>	1	Mild hallucinogen
Marsh marigold	<i>Caltha palustris</i>	3	Irritant oil protoanemonin
Mate	<i>Ilex paraguayensis</i>	1, 3	Irritant tannins; caffeine
Mayapple	<i>Podophyllum peltatum</i>	1, 3	Oil is keratolytic, irritant; hypotension, seizures reported
Meadow crocus	<i>Colchicum autumnale</i>	1	Colchicine (see p 173)
Mescal bean	<i>Sophora secundiflora</i>	1	Cytisine: similar to nicotine (see p 277)
Mescal button	<i>Lophophora williamsii</i>	1	Mescaline: hallucinogen (see p 247)
Milkweed	<i>Asclepias</i> spp	3	Cardiac glycosides (see p 155), myocarditis and neuropathy in animals
Mistletoe, American	<i>Phoradendron flavescens</i>	3	GI upset
Mistletoe, European	<i>Viscum album</i>	1, 3	Hemoagglutination, seizures, GI upset
Mock azalea	<i>Menziesia ferruginea</i>	1	Cardiac glycosides (see p 155)
Monkshood	<i>Aconitum napellus</i>	1	Aconite: hypotension, AV block, arrhythmias; seizures
Moonseed	<i>Menispermaceae</i>	1	Seizures
Moonseed, Carolina	<i>Cocculus carolinus</i>	1	Seizures
Mormon tea	<i>Ephedra viridis</i>	1	Ephedra: tachycardia, hypertension (see p 320)
Morning glory	<i>Ipomoea violacea</i>	1	Seeds are hallucinogenic
Mountain laurel	<i>Kalmia</i> spp	1	Grayanotoxin
Naked lady	<i>Amaryllis belladonna</i>	3	GI upset
Narcissus	<i>Narcissus</i> spp	3	GI upset
Nectarine (chewed pits)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Nephthytis	<i>Syngonium podophyllum</i>	2a	Calcium oxalate crystals
Nightshade	<i>Solanum</i> spp	1, 3	Solanine and anticholinergic alkaloids (see p 84)
Nightshade, black	<i>Solanum nigrum</i> , <i>Hyoscyamus</i> spp	1	Solanine; anticholinergic alkaloids (see p 84)
Nightshade, deadly	<i>Atropa belladonna</i>	1	Atropine (see p 84)
Nutmeg	<i>Myristica fragrans</i>	1	Hallucinogen (see p 247)
Oak	<i>Quercus</i> spp	1	Tannin
Oakleaf ivy	<i>Hedera helix</i>	3	GI upset, dermatitis
Oakleaf ivy	<i>Toxicodendron</i> spp	3	Urushiol oleoresin: contact dermatitis
Oleander	<i>Nerium oleander</i>	1	Cardiac glycosides (see p 155)
Oleander, yellow	<i>Thevetia peruviana</i>	1	Cardiac glycosides (see p 155); more toxic than <i>Nerium</i>
Olive	<i>Olea europaea</i>	3	Dermatitis
Ornamental cherry	<i>Prunus</i> spp	1	Cyanogenic (see p 177)
Ornamental pear	<i>Pyrus calleryana</i>	3	Dermatitis
Ornamental plum (chewed seeds)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Ornamental pepper	<i>Capsicum annuum</i>	3	GI upset, dermatitis
Ornamental pepper	<i>Solanum pseudocapsicum</i>	1	Solanine
Palm (thorns or spines)	various	3	Cellulitis, synovitis
Pampas grass	<i>Cortaderia selloana</i>	1	Cyanogenic glycosides (see p 177)
Paper white narcissus	<i>Narcissus</i> spp	3	GI upset
Paradise tree	<i>Melia azedarach</i>	1, 3	Chinaberry severe GI upset; seizure
Paraguay tea	<i>Ilex paraguayensis</i>	1, 3	Irritant tannins; caffeine (see p 142)
Pasque flower	<i>Anemone</i> spp	1	Protoanemonin
Peach (chewed pits)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Pear (chewed seeds)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Pecan	<i>Carya illinonensis</i>	3	Dermatitis
Pennyroyal (oil)	<i>Mentha pulegium</i>	1	Hepatotoxic, seizures, multi-system failure (see p 147)
Periwinkle	<i>Vinca</i>	1	<i>Vinca</i> alkaloids
Periwinkle, rose	<i>Catharanthus roseus</i>	1	Hallucinogen
Peyote; mescal	<i>Lophophora williamsii</i>	1	Mescaline; hallucinogen (see p 247)
Pheasant's-eye	<i>Adonis</i> spp	1	Cardiac glycosides (see p 155)
Pigeonberry	<i>Duranta repens</i>	3	Saponins
Pigeonberry	<i>Cornus canadensis</i>	3	Dermatitis
Pigeonberry	<i>Rivina humilis</i>	1	Saponin
Pigeonberry	<i>Phytolacca americana</i>	3	Saponin
Plum (chewed pits)	<i>Prunus</i> spp	1	Cyanogenic glycosides (see p 177)
Poinsettia	<i>Euphorbia</i> spp	3	Possible GI upset
Poison ivy; poison oak; poison sumac; poison vine	<i>Toxicodendron</i> spp	3	Urushiol oleoresin contact dermatitis (<i>Rhus</i> dermatitis)
Pokeweed (unripe berries)	<i>Phytolacca americana</i>	3	Saponin
Poplar	<i>Populus</i> spp	3	Dermatitis
Poppy, common	<i>Papaver somniferum</i>	1	Opiates (see p 286)
Potato (unripe, leaves)	<i>Solanum</i> spp	1, 3	Solanine and anticholinergic alkaloids (see p 84)
Pothos	<i>Scindapsus aureus</i>	2a	Calcium oxalate crystals
Pothos	<i>Epipremnum aureum</i>	2a	Calcium oxalate crystals
Prayer bean	<i>Arbus prectorius</i>	1	Toxalbumin
Prickly pear (thorn)	<i>Opuntia</i> spp	3	Dermatitis, cellulitis
Prickly poppy	<i>Argemone mexicana</i>	1	Sanguinaria. Narcotic-analgesic, smoked as euphoriant
Pride of China, Pride of India	<i>Melia azedarach</i>	1	Chinaberry: severe GI upset, seizures
Pride-of-Madeira	<i>Echium</i> spp	1	Pyrrolizidine alkaloids: hepatotoxicity
Primrose	<i>Primula vulgaris</i>	3	Dermatitis
Privet; common privet	<i>Ligustrum</i> spp	3	GI upset
Purge nut	<i>Jatropha curcas</i>	1	Toxalbumin, Euphorbiaceae
Purslane	<i>Portulaca oleracea</i>	2b	Soluble oxalates
Pussy willow	<i>Salix caprea</i>	3	Dermatitis
Pyracantha	<i>Pyracantha</i>	3	GI upset
Queen Anne's Lace	<i>Daucus carota</i>	3	Dermatitis
Ragweed	<i>Ambrosia artemisiifolia</i>	3	Dermatitis
Ragwort, tansy	<i>Senecio</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
Ranunculus	<i>Ranunculus</i> spp	1	Protoanemonin
Rattlebox	<i>Sesbania</i> spp	3	Saponins
Rattlebox, bush tea	<i>Crotalaria</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
Rattlebox, purple	<i>Daubentonia</i> spp	3	Hepatotoxic pyrrolizidine alkaloids
Rattlebush	<i>Baptista tinctoria</i>	1	Cytisine
Redwood tree	<i>Sequoia sempervirens</i>	3	Dermatitis
Rhododendron	<i>Rhododendron</i> genus	1	Grayanotoxin
Rhubarb (leaves)	<i>Rheum rhaponticum</i>	2b	Soluble oxalates
Rosary pea; rosary bean	<i>Abrus precatorius</i>	1	Toxalbumin (abrin): severe fatal gastroenteritis reported
Rose (thorn)	<i>Rosa</i> spp	3	Cellulitis
Rose periwinkle	<i>Catharanthus roseus</i>	1	Vincristine, vinblastine (see p 100)
Rue	<i>Ruta graveolens</i>	3	Dermatitis
Rustyleaf	<i>Menziesia ferruginea</i>	1	Grayanotoxins
Sagebrush	<i>Artemisia</i> spp	1, 3	GI upset; CNS stimulant
Salvia	<i>Salvia divinorum</i>	1	Mild hallucinogen
Sassafras	<i>Sassafras albidum</i>	1	Hepatocarcinogenic
Scotch broom	<i>Cytisus scoparins</i>	1, 3	Cytisine, GI upset

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Shamrock	<i>Oxalis</i> spp	2b	Soluble oxalates
Skunk cabbage	<i>Symplocarpus foetidus</i>	2a	Calcium oxalate crystals
Skunk cabbage	<i>Veratrum</i> spp	1, 3	Veratrum alkaloids
Sky-flower	<i>Duranta repens</i>	3	Saponins
Snakeroot	<i>Eupatorium rugosum</i>	1	Hepatotoxic pyrrolizidine alkaloids
Snakeroot	<i>Cicuta maculata</i>	1	Water hemlock: seizures
Snakeroot	<i>Rauwolfia serpentina</i>	1	Antihypertensive reserpine; tranquilizer
Snowberry	<i>Symphoricarpos</i> spp	3	GI upset
Sorrel	<i>Oxalis</i> spp, <i>Rhumex</i> spp	2b	Soluble oxalate
Soursob	<i>Oxalis</i> spp	2b	Soluble oxalates
Spathiphyllum	<i>Spathiphyllum</i>	2a	Calcium oxalate crystals
Spindle tree	<i>Euonymus</i> spp	3	GI upset
Split leaf philodendron	<i>Philodendron</i> spp	2a	Calcium oxalate crystals
Squill	<i>Scilla</i> ; <i>Urginea maritima</i>	1	Cardiac glycosides (see p 155)
Star-of-Bethlehem	<i>Ornithogalum</i> spp	1	Cardiac glycosides (see p 155)
Star-of-Bethlehem	<i>Hippobroma longiflora</i>	1	Lobeline
St. John's Wort	<i>Hypericum perforatum</i>	1	Mild GI upset; mild serotonin enhancer (see p 215)
String of pearls/beads	<i>Senecio</i> spp	1	Hepatotoxic pyrrolizidine alkaloids
Strychnine	<i>Strychnos nux-vomica</i>	1	Strychnine: seizures (see p 348)
Sweet clover	<i>Mellilotus</i> spp	1	Coumarin glycosides (see p 378)
Sweet pea	<i>Lathyrus odoratus</i>	1	Neuropathy (lathyrism) after chronic use
Sweet William	<i>Dianthus barbatus</i>	3	GI upset, dermatitis
Swiss cheese plant	<i>Monstera friedrichsthali</i>	2a	Calcium oxalate crystals
Tansy	<i>Tanacetum</i> spp	3	Dermatitis
Taro	<i>Alocasia macrorrhia</i>	2a	Oxalate crystals
Taro	<i>Colocasia esculenta</i>	2a	Oxalate crystals
Texas umbrella tree	<i>Melia azedarach</i>	1	Chinaberry: severe GI upset; seizures
Thornapple	<i>Datura stramonium</i>	1	Anticholinergic (see p 84)
Tobacco	<i>Nicotiana</i> spp	1	Nicotine (see p 277)
Tobacco, wild	<i>Lobelia inflata</i>	1	Lobeline
Tomato (leaves)	<i>Lycopersicon esculentum</i>	1	Solanine
Tonka bean	<i>Dipteryx odorata</i>	1	Coumarin glycosides (see p 378)
Toyon (leaves)	<i>Heteromeles arbutifolia</i>	1	Cyanogenic glycosides (see p 177)
Tulip (bulb)	<i>Tulipa</i>	3	Dermatitis
Tung nut, tung tree; candle nut	<i>Aleurites</i> spp	1, 3	Euphorbiaceae
Turbina	<i>Turbina corymbosa</i>	1	Hallucinogen
T'u-san-chi	<i>Gynura segetum</i>	1	Hepatotoxic pyrrolizidine alkaloids
Umbrella plant	<i>Cyperus alternifolius</i>	1	Acute: gastrointestinal. Chronic: renal toxicity, seizures
Uva-ursi	<i>Arctostaphylos uva-ursi</i>	1, 3	Hydroquinone: berries edible
Valerian	<i>Valeriana officinalis</i>	1	Valerine alkaloids: used as mild tranquilizer
Verbena	<i>Verbena officinalis</i> and <i>hastata</i>	3	Dermatitis
Virginia creeper	<i>Parthenocissus</i> spp	2b	Soluble oxalates
Walnut (green shells)	<i>Juglans</i>	3	Dermatitis
Water hemlock	<i>Cicuta maculata</i>	1	Cicutoxin: seizures
Weeping fig (sap)	<i>Ficus benjamina</i>	3	Dermatitis
Weeping willow	<i>Salix babylonica</i>	3	Dermatitis
White cedar	<i>Melia azedarach</i>	1	Chinaberry: severe GI upset; seizures
White cedar	<i>Hura crepitans</i>	3	GI upset, dermatitis
Wild calla	<i>Calla palustris</i>	2b	Soluble oxalates
Wild cotton	<i>Asclepias syriaca</i>	1	Cardiac glycosides (see p 155)
Wild onion	<i>Zigadenus</i> spp	1	GI upset, dermatitis
Windflower	<i>Anemone</i>	3	Irritant oil protoanemonin
Wisteria	<i>Wisteria</i>	3	GI upset

(continued)

TABLE II-46. POISONOUS PLANTS (CONTINUED)

Common Name	Botanical Name	Toxic Group	Remarks (see text and Table II-45)
Woodbind	<i>Parthenocissus</i> spp	2b	Soluble oxalates
Woodruff	<i>Galium odoratum</i>	1	Coumarin glycosides (see p 378)
Wood rose	<i>Ipomoea violacea</i> ; <i>Merremia tuberosa</i>	1	Seeds are hallucinogenic
Wormwood	<i>Artemisia absinthium</i>	1	Absinthe: possible CNS effects, porphyria with chronic use
Yarrow	<i>Achillea millefolium</i>	3	GI upset, dermatitis
Yellow oleander	<i>Thevetia peruviana</i>	1	Cardiac glycosides (see p 155)
Yew	<i>Taxus</i>	1	Taxine; similar to cardiac glycosides (see p 155); seizures
Yohimbine	<i>Corynanthe yohimbe</i>	1	Purported aphrodisiac; mild hallucinogen; α_2 -adrenergic blocker

- C. Group 2b.** Soluble oxalates may be absorbed into the circulation, where they precipitate with calcium. Acute hypocalcemia and multiple-organ injury, including renal tubular necrosis, may result (see Oxalates, p 295).
- D. Group 3.** Skin or mucous membrane irritation may occur, although it is less severe than with group 2 plants. Vomiting and diarrhea are common but are usually mild to moderate and self-limited. Fluid and electrolyte imbalances caused by severe gastroenteritis are rare.
- IV. Diagnosis** is usually based on a history of exposure and when plant material is seen in vomitus. Identification of the plant is often difficult. Because common names sometimes refer to more than one plant, it is preferable to confirm the botanical name. If in doubt about the plant identification, take a cutting of the plant (not just a leaf or a berry) to a local nursery, florist, or college botany department.
- A. Specific levels.** Serum toxin levels are not available for most plant toxins. In selected cases, laboratory analyses for therapeutic drugs may be used (eg, digoxin assay for oleander glycosides; cyanide level for cyanogenic glycosides).
- B. Other useful laboratory studies** for patients with gastroenteritis include CBC, electrolytes, glucose, BUN, creatinine, and urinalysis. If hepatotoxicity is suspected, obtain liver transaminases and prothrombin time (PT, INR).
- V. Treatment.** Most ingestions cause no symptoms or only mild gastroenteritis. Patients recover quickly with supportive care.
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Treat coma (see p 19), seizures (p 22), arrhythmias (pp 10–15), and hypotension (p 16) if they occur.
 3. Replace fluid losses caused by gastroenteritis with intravenous crystalloid solutions.
- B. Specific drugs and antidotes.** There are few effective antidotes. Refer to additional discussions elsewhere in Section II for further details.
- C. Decontamination** (see page 46)
1. **Group 1 and group 2b plants**
 - a. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 - b. **Hospital.** Administer activated charcoal. Gastric lavage is not necessary if activated charcoal can be given promptly.
 2. **Group 2a and group 3 plants**
 - a. Wash the affected areas with soap and water and give water to drink.

- b. Administer ice cream, juice bars, pudding, or cold milk to soothe irritated oral mucous membranes after exposure to insoluble oxalate plants.
- c. Do **not** induce vomiting, because of potential aggravation or irritant effects. Gastric lavage and activated charcoal are not necessary.

D. Enhanced elimination. These procedures are generally not effective.

Krenzelok EP et al: Contrary to the literature, vomiting is not a common manifestation associated with plant exposures. *Vet Hum Toxicol* 2002;44(5):298–300. [PMID: 12361120] (Based on review of national poison center data, 10 plants accounted for 32.3% of the reports of vomiting: *Philodendron*, *Spathiphyllum*, *Narcissus*, *Dieffenbachia*, *Phytolacca*, *Epipremnum*, *Euphorbia*, *Eucalyptus*, *Ficus*, and *Hedera*.)

Mrvos R et al: Toxicidromes associated with the most common plant ingestions. *Vet Human Toxicol* 2001;43:366. [PMID: 11757998] (Review of toxic syndromes associated with 20 common plant exposures, based on review of over 700,000 calls to poison control centers.)

► POLYCHLORINATED BIPHENYLS (PCBs)

Diane Liu, MD, MPH

Polychlorinated biphenyls (PCBs) are a group of chlorinated hydrocarbon compounds that were once widely used as high-temperature insulators for transformers and other electrical equipment and were also found in carbonless copy papers and some inks and paints. Since 1974, all uses in the United States are confined to closed systems. Most PCB poisonings are chronic occupational exposures, with delayed-onset symptoms being the first indication that an exposure has occurred. In 1977, the US Environmental Protection Agency (EPA) banned further manufacturing of PCBs because they are suspected carcinogens and are highly persistent.

- I. **Mechanism of toxicity.** PCBs are irritating to mucous membranes. When burned, PCBs may produce the more highly toxic polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs; see p 184). It is difficult to establish the specific effects of PCB intoxication because PCBs are nearly always contaminated with small amounts of these compounds. PCBs, and particularly the PCDD and PCDF contaminants, are mutagenic and teratogenic and are considered potential human carcinogens.
- II. **Toxic dose.** PCBs are well absorbed by all routes (skin, inhalation, and ingestion) and are widely distributed in fat; bioaccumulation occurs even with low-level exposure.
 - A. **Inhalation.** PCBs are mildly irritating to the skin at airborne levels of 0.1 mg/m³ and very irritating at 10 mg/m³. The recommended workplace limits (ACGIH TLV-TWA) are 0.5 mg/m³ (for PCBs with 54% chlorine) and 1 mg/m³ (for PCBs with 42% chlorine) as 8-hour time-weighted averages. The air level considered immediately dangerous to life or health (IDLH) for either type is 5 mg/m³.
 - B. **Ingestion.** Acute toxicity after ingestion is unlikely; the oral LD₅₀ is 1–10 g/kg.
- III. **Clinical presentation**
 - A. **Acute PCB exposure** may cause skin, eye, nose, and throat irritation.
 - B. **Chronic exposure** may cause **chloracne** (cystic acneiform lesions predominantly found on the posterior neck, axillae, and upper back); the onset is usually 6 weeks or longer after exposure. Skin pigmentation and porphyria may occur. Elevation of hepatic transaminases may occur.
 - C. Epidemiological studies suggest that PCB exposure can be associated with neurobehavioral effects in newborns and children.
- IV. **Diagnosis** is usually based on a history of exposure and the presence of chloracne or elevated hepatic transaminases.
 - A. **Specific levels.** PCB serum and fat levels are poorly correlated with health effects. Serum PCB concentrations are usually less than 20 mcg/L; higher levels may indicate exposure but not necessarily toxicity.
 - B. **Other useful laboratory studies** include BUN, creatinine, and liver enzymes.

V. Treatment

A. Emergency and supportive measures

1. Treat bronchospasm (see p 8) if it occurs.
2. Monitor for elevated hepatic enzymes; chloracne; and nonspecific eye, gastrointestinal, and neurologic symptoms.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
2. **Skin and eyes.** Remove contaminated clothing and wash exposed skin with soap and water. Irrigate exposed eyes with copious tepid water or saline.
3. **Ingestion (see p 47)**
 - a. **Prehospital.** Administer activated charcoal if available. Ipecac-induced vomiting may be useful for initial treatment if it can be given within a few minutes of exposure.
 - b. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination. There is no role for dialysis, hemoperfusion, or repeat-dose charcoal. Lipid-clearing drugs (eg, clofibrate and resins) have been suggested, but insufficient data exist to recommend them.

Faroon O: Effects of polychlorinated biphenyls on the nervous system. *Toxicol Ind Health* 2001;16(7-8):305-333. [PMID: 11693948] (Review.)

► PSEUDOEPHEDRINE, EPHEDRINE, AND OTHER DECONGESTANTS

Neal L. Benowitz, MD

Pseudoephedrine, ephedrine, and phenylephrine are sympathomimetic drugs widely available in nonprescription nasal decongestants and cold preparations. These remedies usually also contain antihistamines and cough suppressants. **Phenylpropanolamine (PPA)** had been marketed as a nonprescription decongestant and appetite suppressant for many years, but was recently removed from the US market because of an association with hemorrhagic stroke in women. Combinations of nonprescription sympathomimetics and caffeine have been sold on the underground market as amphetamine or cocaine substitutes. Ephedrine and ephedra-containing herbal preparations (eg, *Ma huang* or "Herbal Ecstasy"), often in combination with caffeine, are used as alternatives to the amphetamine derivative Ecstasy (see p 72) or as adjuncts to body-building or weight-loss programs.

I. Mechanism of toxicity. All these agents stimulate the adrenergic system, with variable effects on alpha- and beta-adrenergic receptors depending on the compound. Generally, these agents stimulate the central nervous system much less than other phenylethylamines (see amphetamines, p 72).

A. PPA and phenylephrine are direct alpha-adrenergic agonists. In addition, PPA produces mild beta-1 adrenergic stimulation and acts in part indirectly by enhancing norepinephrine release.

B. Ephedrine and pseudoephedrine have both direct and indirect alpha- and beta-adrenergic activity but clinically produce more beta-adrenergic stimulation than PPA or phenylephrine.

C. Pharmacokinetics. Peak effects occur within 1-3 hours although absorption may be delayed with sustained-release products. The drugs have large volumes of distribution (eg, the Vd for PPA is 2.5-5 L/kg). Elimination half-lives are 3-7 hours. See also Table II-59, p 381.

II. Toxic dose. Table II-47 lists the usual therapeutic doses of each agent. Patients with autonomic insufficiency and those taking monoamine oxidase (MAO) in-

TABLE II-47. COMMON OVER-THE-COUNTER SYMPATHOMIMETIC DRUGS

Drug	Major Effects ^a	Usual Daily Adult Dose (mg)	Usual Daily Pediatric Dose (mg/kg)
Ephedrine	beta, alpha	100–200	2–3
Phenylephrine	alpha	40–60	0.5–1
Phenylpropanolamine ^b	alpha	100–150	1–2
Pseudoephedrine	beta, alpha	180–360	3–5

^aalpha = alpha-adrenergic receptor agonist; beta = beta-adrenergic receptor agonist.

^bRemoved from US market.

hibitors (see p 269) may be extraordinarily sensitive to these and other sympathomimetic drugs, developing severe hypertension after ingestion of even subtherapeutic doses.

A. PPA, phenylephrine, and ephedrine have low toxic:therapeutic ratios. Toxicity often occurs after ingestion of just 2–3 times the therapeutic dose. Strokes and cardiac toxicity have been reported after therapeutic doses of ephedra and PPA.

B. Pseudoephedrine is less toxic, with symptoms occurring after four- to fivefold the usual therapeutic dose.

III. **Clinical presentation.** The time course of intoxication by these drugs is usually brief, with resolution within 4–6 hours (unless sustained-release preparations are involved). The major toxic effect of these drugs is **hypertension**, which may lead to headache, confusion, seizures, and intracranial hemorrhage.

A. **Intracranial hemorrhage** may occur in normal, healthy young persons after what might appear to be only modest elevation of the blood pressure (ie, 170/110 mm Hg) and is often associated with focal neurologic deficits, coma, or seizures.

B. **Bradycardia or atrioventricular block** is common in patients with moderate to severe hypertension associated with PPA and phenylephrine, owing to the baroreceptor reflex response to hypertension. The presence of drugs such as antihistamines or caffeine prevents reflex bradycardia and may enhance the hypertensive effects of PPA and phenylephrine.

C. **Myocardial infarction** and diffuse myocardial necrosis have been associated with ephedra use and PPA intoxication.

IV. **Diagnosis** is usually based on a history of ingestion of diet pills or decongestant medications and the presence of hypertension. Bradycardia or AV block suggests PPA or phenylephrine. Severe headache, focal neurologic deficits, or coma should raise the possibility of intracerebral hemorrhage.

A. **Specific levels.** Serum drug levels are not generally available and do not alter treatment. These agents may produce positive results for amphetamines on urine testing (see Table I-33, p 43), but can be distinguished on confirmatory testing.

B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, CPK with MB isoenzymes, 12-lead ECG and ECG monitoring, and CT head scan if intracranial hemorrhage is suspected.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat hypertension aggressively (see p 17 and B, below). Treat seizures (p 22) and ventricular tachyarrhythmias (p 13) if they occur. Do **not** treat reflex bradycardia, except indirectly by lowering blood pressure.

3. Monitor the vital signs and ECG for a minimum of 4–6 hours after exposure, and longer if a sustained-release preparation has been ingested.

B. Specific drugs and antidotes

1. **Hypertension.** Treat hypertension if the diastolic pressure is higher than 100–105 mm Hg, especially in a patient with no prior history of hypertension. If there is computed tomographic or obvious clinical evidence of intracranial hemorrhage, lower the diastolic pressure cautiously, to no lower than 90 mm Hg, and consult a neurosurgeon immediately.
 - a. Use a vasodilator such as **phentolamine** (see p 487) or **nitroprusside** (p 477).
 - b. **Caution:** Do **not** use beta-blockers alone to treat hypertension without first giving a vasodilator; paradoxical worsening of the hypertension may result.
 - c. Many patients have moderate orthostatic variation in the blood pressure; therefore, for immediate partial relief of severe hypertension, try placing the patient in an upright position.
2. **Arrhythmias**
 - a. Tachyarrhythmias usually respond to low-dose **esmolol** (see p 443) or **metoprolol**.
 - b. **Caution:** Do **not** treat AV block or sinus bradycardia associated with hypertension; increasing the heart rate with atropine may abolish this reflex response that serves to limit hypertension, resulting in worsening elevation of the blood pressure.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.

D. Enhanced elimination.

Dialysis and hemoperfusion are not effective. Urinary acidification may enhance elimination of PPA, ephedrine, and pseudoephedrine, but may also aggravate myoglobin deposition in the kidney if the patient has rhabdomyolysis.

Haller CA, Benowitz NL: Adverse cardiovascular and central nervous system events associated with dietary supplements containing ephedra alkaloids. *N Engl J Med* 2000;343(25):1833–1838. [PMID: 11117974] (Review of 140 reports submitted to the FDA included hypertension, stroke, and seizures. There were 10 deaths and 13 patients had permanent disability.)

Kernan WN et al: Phenylpropanolamine and the risk of hemorrhagic stroke. *N Engl J Med* 2000;343(25):1826–1832. [PMID: 11117973] (Case-control study of 702 patients with hemorrhagic stroke found an adjusted odds ratio of 16.58 for the use of a PPA-containing appetite suppressant.)

► PYRETHRINS AND PYRETHROIDS

John P. Lamb, PharmD

Pyrethrins are naturally occurring insecticides derived from the chrysanthemum plant. Pyrethroids (Table II–48) are synthetically derived compounds. Acute human poisoning from exposure to these insecticides is rare; however, they can cause skin and upper-airway irritation and hypersensitivity reactions. Piperonyl butoxide is added to these compounds to prolong their activity by inhibiting mixed oxidase enzymes in the liver that metabolize the pyrethrins. Common pyrethrin-containing pediculicides include A-200, Triple-X, and RID.

1. **Mechanism of toxicity.** In insects, pyrethrins and pyrethroids rapidly cause death by paralyzing the nervous system through disruption of the membrane ion transport system in nerve axons, and pyrethroids prolong sodium influx and also

TABLE II-48. PYRETHROIDS

Allethrin	Cypermethrin	Furamethrin
Barthrin	Decamethrin	Permethrin
Bioallethrin	Deltamethrin	Phthalthrin
Bioresmethrin	Dimethrin	Resmethrin
Cismethrin	Fenothrin	Supermethrin
Cymethrin	Fenvalerate	Tetramethrin

may block inhibitory pathways. Mammals are generally able to metabolize these compounds rapidly and thereby render them harmless.

- II. Toxic dose.** The toxic oral dose in mammals is greater than 100–1000 mg/kg, and the potentially lethal acute oral dose is 10–100 g. Pyrethrins are not well absorbed across the skin or from the gastrointestinal tract. They have been used for many years as oral anthelmintic agents with minimum adverse effects other than mild gastrointestinal upset.

A. Deltamethrin. There is one report of seizures in a young woman who ingested 30 mL of 2.5% deltamethrin (750 mg). **Miraculous Insecticide Chalk™** (from China) contains up to 37.6 mg of deltamethrin per stick of chalk. Ingestion of a single chalk is generally considered nontoxic.

B. A 45-year-old man died after ingesting beans cooked in 10% cypermethrin.

- III. Clinical presentation.** Toxicity to humans is primarily associated with hypersensitivity reactions and direct irritant effects rather than any pharmacologic property.

A. Anaphylactic reactions including bronchospasm, oropharyngeal edema, and shock may occur in hypersensitive individuals.

B. Inhalation of these compounds may precipitate wheezing in asthmatics. An 11-year-old girl had a fatal asthma attack after applying a pyrethrin-containing shampoo to her dog. Inhalation or pulmonary aspiration may also cause a hypersensitivity pneumonitis.

C. Skin exposure may cause burning, tingling, numbness, and erythema. The paresthesias are believed to result from a direct effect on cutaneous nerve endings.

D. Eyes. Accidental eye exposure during scalp application of A-200 Pynrate has caused corneal injury including keratitis and denudation. The cause is uncertain, but may be related to the surfactant (Triton-X) contained in the product.

E. Ingestion. With large ingestions (200–500 mL of concentrated solution), the central nervous system (CNS) may be affected, resulting in seizures, coma, or respiratory arrest.

- IV. Diagnosis** is based on a history of exposure. There are no characteristic clinical symptoms or laboratory tests that are specific for identifying these compounds.

A. Specific levels. These compounds are rapidly metabolized in the body, and methods for determining the parent compound are not routinely available.

B. Other useful laboratory studies include electrolytes, glucose, and arterial blood gases or oximetry.

V. Treatment

A. Emergency and supportive measures

1. Treat bronchospasm (see p 8) or anaphylaxis (p 27) if they occur.
2. Observe patients with a history of large ingestions for at least 4–6 hours for any signs of CNS depression or seizures.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Inhalation.** Remove victims from exposure and give supplemental oxygen if needed.
2. **Skin.** Wash with copious soap and water. Topical application of vitamin E in vegetable oil was reported anecdotally to relieve paresthesias.

3. **Eyes.** Irrigate with copious water. After irrigation, perform a fluorescein examination and refer the victim to an ophthalmologist if there is evidence of corneal injury.
4. **Ingestion** (see p 48). In the majority of cases, a subtoxic dose has been ingested and no decontamination is necessary. However, after a large ingestion of Chinese chalk or a concentrated solution:

a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of the risk of lethargy, seizures, or aspiration of hydrocarbon solvent.

b. **Hospital.** Administer activated charcoal. Gastric lavage is not necessary if activated charcoal can be given promptly.
- D. **Enhanced elimination.** These compounds are rapidly metabolized by the body, and extracorporeal methods of elimination would not be expected to enhance their elimination.

Wagner SL: Fatal asthma in a child after use of an animal shampoo containing pyrethrin. *West J Med* 2000;173(2):86–87. [PMID: 10924422] (Case report. The shampoo contained 0.2% pyrethrin.)

Wilks MF: Pyrethroid-induced paresthesia—a central or local toxic effect? *J Toxicol Clin Toxicol* 2000;38(2):103–105. [PMID: 10778905] (Review of reports of pyrethroid-induced paresthesias concludes that they result from local effects on cutaneous nerve endings.)

► **QUINIDINE AND OTHER TYPE Ia ANTIARRHYTHMIC DRUGS**

Neal L. Benowitz, MD

Quinidine, procainamide (Pronestyl™), and disopyramide (Norpace™) are type Ia antiarrhythmic agents. Quinidine and procainamide are commonly used for suppression of supraventricular and ventricular arrhythmias. Disopyramide is used for ventricular arrhythmias. All three agents have a low toxic:therapeutic ratio and may produce fatal intoxication (Table II–49). See description of other antiarrhythmic agents on p 78.

- I. **Mechanism of toxicity**
- A. Type Ia agents depress the fast sodium-dependent channel, slowing phase zero of the cardiac action potential. At high concentrations, this results in reduced myocardial contractility and excitability, and severe depression of cardiac conduction velocity. Repolarization is also delayed, resulting in a prolonged QT interval that may be associated with polymorphic ventricular tachycardia (torsade de pointes; see Figure I–7, p 15).
- B. Quinidine and disopyramide also have anticholinergic activity; quinidine has alpha-adrenergic receptor-blocking activity, and procainamide has ganglionic- and neuromuscular-blocking activity.

TABLE II–49. TYPE Ia ANTIARRHYTHMIC DRUGS

Drug	Serum Half-Life (h)	Usual Adult Daily Dose (mg)	Therapeutic Serum Levels (mg/L)	Major Toxicity ^a
Quinidine	6–8	1000–2000	2–4	S, B, V, H
Disopyramide	4–10	400–800	2–4	B, V, H
Procainamide	4	1000–4000	4–10	B, V, H
NAPA ^b	5–7	N/A	15–25	H

^aS = seizures; B = bradycardia; V = ventricular tachycardia; H = hypotension.

^bNAPA = *N*-acetylprocainamide, an active metabolite of procainamide.

- C. Pharmacokinetics.** See Table II–59, p 381.
- II. Toxic dose.** Acute adult ingestion of 1 g of quinidine, 5 g of procainamide, or 1 g of disopyramide, and any ingestion in children, should be considered potentially lethal.
- III. Clinical presentation.** The primary manifestations of toxicity involve the cardiovascular and central nervous systems.
- A. Cardiotoxic effects** of the type Ia agents include sinus bradycardia; sinus node arrest or asystole; PR, QRS, or QT interval prolongation; sinus tachycardia (caused by anticholinergic effects); polymorphous ventricular tachycardia (torsade de pointes); and depressed myocardial contractility, which, along with alpha-adrenergic or ganglionic blockade, may result in hypotension and occasionally pulmonary edema.
- B. Central nervous system toxicity.** Quinidine and disopyramide can cause anticholinergic effects such as dry mouth, dilated pupils, and delirium. All type Ia agents can produce seizures, coma, and respiratory arrest.
- C. Other effects.** Quinidine commonly causes nausea, vomiting, and diarrhea after acute ingestion and, especially with chronic doses, cinchonism (tinnitus, vertigo, deafness, or visual disturbances). Procainamide may cause gastrointestinal upset and, with chronic therapy, a lupus-like syndrome.
- IV. Diagnosis** is based on a history of exposure and typical cardiotoxic features such as QRS and QT interval prolongation, AV block, or polymorphous ventricular tachycardia.
- A. Specific levels.** Serum levels are generally available for each agent. Serious toxicity with these drugs usually occurs only with levels above the therapeutic range; however, some complications, such as QT prolongation and polymorphous ventricular tachycardia, may occur at therapeutic levels.
1. Methods for detecting quinidine may vary in specificity, with some also measuring metabolites and contaminants.
 2. Procainamide has an active metabolite, *N*-acetylprocainamide (NAPA); with therapeutic procainamide dosing, NAPA levels can range from 15 to 25 mg/L.
- B. Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, arterial blood gases or oximetry, and ECG monitoring.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat hypotension (see p 16), arrhythmias (pp 10–15), coma (p 19), and seizures (p 22) if they occur.
 3. Treat recurrent ventricular tachycardia with lidocaine, phenytoin, or overdrive pacing (p 13). Do **not** use other type Ia or Ic agents, because they may worsen cardiac toxicity.
 4. Continuously monitor vital signs and ECG for a minimum of 6 hours, and admit symptomatic patients until the ECG returns to normal.
- B. Specific drugs and antidotes.** Treat cardiotoxic effects such as wide QRS intervals or hypotension with **sodium bicarbonate** (see p 419), 1–2 mEq/kg rapid IV bolus, repeated every 5–10 minutes and as needed. Markedly impaired conduction or high-degree atrioventricular (AV) block unresponsive to bicarbonate therapy is an indication for insertion of a cardiac pacemaker.
- C. Decontamination** (see p 47)
1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures and coma.
 2. **Hospital.** Administer activated charcoal. Consider gastric lavage for large ingestions.
- D. Enhanced elimination** (see p 54)
1. **Quinidine** has a very large volume of distribution, and therefore it is not effectively removed by dialysis. Acidification of the urine may enhance excretion, but this is not recommended because it may aggravate cardiac toxicity.

2. **Disopyramide, procainamide, and N-acetylprocainamide (NAPA)** have smaller volumes of distribution and are effectively removed by hemoperfusion or dialysis.
3. The efficacy of repeat-dose activated charcoal has not been studied for the type Ia agents.

Tecklenburg FW et al: Pediatric ECMO for severe quinidine cardiotoxicity. *Pediatr Emerg Care* 1997;13(2):111–113. [PMID: 9127419] (Case report of successful use of ECMO in a 16-month-old child with severe quinidine cardiotoxicity.)

► QUININE

Neal L. Benowitz, MD

Quinine is an optical isomer of quinidine. Quinine was once widely used for treatment of malaria and is still occasionally used for chloroquine-resistant cases, but it is now prescribed primarily for the treatment of nocturnal muscle cramps. Quinine is found in tonic water and has been used to cut street heroin. It has also been used as an abortifacient.

- I. **Mechanism of toxicity.** The mechanism of quinine toxicity is believed to be similar to that of quinidine (see p 324); however, quinine is a much less potent cardiotoxin. Quinine also has toxic effects on the retina that can result in blindness. At one time, vasoconstriction of retinal arterioles resulting in retinal ischemia was thought to be the cause of blindness; however, recent evidence indicates a direct toxic effect on photoreceptor and ganglion cells.
- II. **Toxic dose.** Quinine sulfate is available in capsules and tablets containing 130–325 mg. The minimum toxic dose is approximately 3–4 g in adults; 1 g has been fatal in a child.
- III. **Clinical presentation.** Toxic effects involve the cardiovascular and central nervous systems, the eyes, and other organ systems.
 - A. **Mild intoxication** produces nausea, vomiting, and cinchonism (tinnitus, deafness, vertigo, headache, and visual disturbances).
 - B. **Severe intoxication** may cause ataxia, obtundation, convulsions, coma, and respiratory arrest. With massive intoxication, quinidine-like cardiotoxicity (hypotension, QRS and QT interval prolongation, AV block, and ventricular arrhythmias) may be fatal.
 - C. **Retinal toxicity** occurs 9–10 hours after ingestion and includes blurred vision, impaired color perception, constriction of visual fields, and blindness. The pupils are often fixed and dilated. Fundoscopy may reveal retinal artery spasm, disk pallor, and macular edema. Although gradual recovery occurs, many patients are left with permanent visual impairment.
 - D. **Other toxic effects** of quinine include hypokalemia, hypoglycemia, hemolysis (in patients with glucose-6-phosphate dehydrogenase [G6PD] deficiency), and congenital malformations when used in pregnancy.
- IV. **Diagnosis** is based on a history of ingestion and the presence of cinchonism and visual disturbances. Quinidine-like cardiotoxic effects may or may not be present.
 - A. **Specific levels.** Serum quinine levels can be measured by the same assay as for quinidine, as long as quinidine is not present. Plasma quinine levels above 10 mg/L have been associated with visual impairment; 87% of patients with levels above 20 mg/L reported blindness. Levels above 16 mg/L have been associated with cardiac toxicity.
 - B. **Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, arterial blood gases or oximetry, and ECG monitoring.
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).

2. Treat coma (see p 19), seizures (p 22), hypotension (p 16), and arrhythmias (pp 10–15) if they occur.
 3. Avoid types Ia and Ic antiarrhythmic drugs; they may worsen cardiotoxicity.
 4. Continuously monitor vital signs and the ECG for at least 6 hours after ingestion, and admit symptomatic patients to an intensive care unit.
- B. Specific drugs and antidotes**
1. Treat cardiotoxicity with **sodium bicarbonate** (see p 419), 1–2 mEq/kg by rapid IV bolus.
 2. Stellate ganglion block has previously been recommended for quinine-induced blindness, the rationale being to increase retinal blood flow. However, recent evidence indicates that this treatment is not effective, and the procedure may have serious complications.
- C. Decontamination** (see p 47)
1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of abrupt onset of seizures or coma.
 2. **Hospital.** Administer activated charcoal. Consider gastric lavage for large ingestions.
- D. Enhanced elimination.** Because of extensive tissue distribution (volume of distribution is 3 L/kg), dialysis and hemoperfusion procedures are ineffective. Acidification of the urine may slightly increase renal excretion but does not significantly alter the overall elimination rate and may aggravate cardiotoxicity.

► RADIATION (IONIZING)

Evan T. Wythe, MD

Radiation poisoning is a rare but potentially challenging complication of the nuclear age. Dependence on nuclear energy, and the expanded use of radioactive isotopes in industry and medicine, increase the possibility of accidental exposures. Ionizing radiation may be generated from a variety of sources. **Particle-emitting** sources may produce beta and alpha particles and neutrons. **Ionizing electromagnetic** radiation includes gamma rays and x-rays. In contrast, magnetic fields, microwaves, radio waves, and ultrasound are examples of **nonionizing** electromagnetic radiation.

Management of a radiation accident depends on whether the victim has been contaminated or only irradiated. **Irradiated** victims pose no threat to health-care providers and may be managed with no special precautions. On the other hand, **contaminated** victims must be decontaminated to prevent spread of radioactive materials to others and the environment.

A terrorist “**dirty bomb**” (dispersion bomb) would likely contain commonly acquired radioactive materials such as cobalt, iridium, and cesium. Psychological effects (ie, panic) would likely overshadow medical concerns, as significant radiation exposure by contamination would be confined to the immediate blast area.

I. Mechanism of toxicity

- A. Radiation impairs biologic function by ionizing atoms and breaking chemical bonds, leading to the formation of highly reactive free radicals that can damage cell walls, organelles, and DNA. Affected cells are either killed or inhibited in division. Cells with a high turnover rate (eg, bone marrow, epithelial coverings such as skin, gastrointestinal tract, and pulmonary system) are more sensitive to radiation. Lymphocytes are particularly sensitive.
- B. Radiation also causes a poorly understood inflammatory response and microvascular effects after moderately high doses (eg, 600 rad).
- C. Radiation effects may be deterministic or stochastic. Deterministic effects are associated with a threshold dose and usually occur within an acute time

frame (within a year). Stochastic effects have no known threshold and may occur after a latency period of years (eg, cancer).

II. Toxic dose. Various terms are used to describe radiation exposure and dose: **R** (roentgen) is a measure of exposure, whereas **rad** (radiation absorbed dose) and **rem** (radiation equivalent, man) are measures of dose. Rad is the unit of radiation dose commonly referred to in exposures, whereas rem is useful in describing dose-equivalent biologic damage. For most exposures, these units can be considered interchangeable. The exception is alpha particle exposure (eg, plutonium), which causes greater double-stranded DNA damage and a higher rem compared with rad.

A. Toxicity thresholds

1. **Acute effects.** Exposure to more than 75 rad causes nausea and vomiting. Exposure to more than 400 rad is potentially lethal without medical intervention. Vomiting within 1–5 hours of exposure suggests an exposure of at least 600 rad. Brief exposure to 5000 rad or more usually causes death within minutes to hours.
2. **Carcinogenesis.** Radiation protection organizations have not agreed on a threshold dose for stochastic effects such as cancer.

B. Recommended exposure limits

1. **Exposure to the general population.** The National Council on Radiation Protection (NCRP) recommends a maximum of 0.5 rem per person per year. The background radiation level at sea level is about 35 millirem (0.035 rem) per year.
2. **Occupational exposure to x-rays.** The federal government has set standards for such exposures: 5 rem/year to the total body, gonads, or blood-forming organs; 75 rem/year to the hands or feet. A single chest x-ray results in a radiation exposure of about 15 millirem (mrem) to the patient, and about 0.006 mrem to nearby health care personnel (at a distance of 160 cm). A head CT scan gives about 1 rad to the head; an abdominal CT scan may give as much as 2–5 rad to the area of concern.
3. **Radiation during pregnancy.** Established guidelines vary but generally recommend a maximum exposure of no more than 50 mrem per month (NCRP). Exposure to the ovaries and fetus from a routine abdominal (KUB) film may be as high as 146 mrem; from a chest x-ray, the dose is about 15 mrem.
4. **Exposure guidelines for emergency health care personnel.** To save a life, the NCRP-recommended maximum exposure for a rescuer is 50 rem whole-body exposure.

III. Clinical presentation

A. Acute radiation syndrome (ARS) consists of a constellation of symptoms and signs indicative of systemic radiation injury. It is often described in four stages (prodrome, latency, manifest illness, and recovery). The onset and severity of each stage of radiation poisoning are determined largely by the dose.

1. The *prodromal* stage, from 0–48 hours, may include nausea, vomiting, abdominal cramps, and diarrhea. Severe exposures are associated with diaphoresis, disorientation, fever, ataxia, coma, shock, and death.
2. During the *latent* stage, there may be an improvement in symptoms. The duration of this stage is usually hours to days, but may be shorter or absent with massive exposures.
3. The *manifest illness* stage, from 1 to 60 days, is characterized by multiple organ system involvement, particularly bone marrow suppression, which may lead to sepsis and death.
4. The *recovery* phase may be accompanied by hair loss, disfiguring burns, and scars.

B. Gastrointestinal system. Exposure to 100 R or more usually produces nausea, vomiting, abdominal cramps, and diarrhea within a few hours. After exposure to 600 rad or more, loss of integrity of the GI mucosal layer results in

denudation and severe necrotic gastroenteritis, which may lead to marked dehydration, gastrointestinal bleeding, and death within a few days. Doses of 1500 rad are thought to completely destroy gastrointestinal stem cells.

C. Central nervous system. With acute exposures of several thousand rad, confusion and stupor may occur, followed within minutes to hours by ataxia, convulsions, coma, and death. In animal models of massive exposure, a phenomenon known as “early transient incapacitation” occurs.

D. Bone marrow depression may be subclinical but apparent on a CBC after exposure to as little as 25 rad. Immunocompromise usually follows exposure to more than 100 rad.

1. Early neutropenia is caused by margination; the true nadir occurs at about 30 days or as soon as 14 days after severe exposure. Neutropenia is the most significant factor in septicemia.

2. Thrombocytopenia is usually not evident for 2 weeks or more after exposure.

3. The lymphocyte count is of great prognostic importance and usually reaches a nadir within 48 hours of serious exposure; a count of less than 300–500 lymphocytes/mm³ during this period indicates a poor prognosis, while 1200/mm³ or more suggests likely survival.

E. Other complications of high-dose acute radiation syndrome include multi-system organ failure, veno-occlusive disease of the liver, interstitial pneumonitis, renal failure, tissue fibrosis, skin burns, and hair loss.

IV. Diagnosis depends on the history of exposure. The potential for contamination should be assessed by determining the type of radionuclide involved and the potential route(s) of exposure.

A. Specific levels

1. **Detection.** Depending on the circumstances, the presence of radionuclides may be verified by one or more of the following devices: survey meters with either pancake or alpha probes, whole-body counts, chest counts, or nuclear medicine cameras.

2. **Biologic specimens.** Nasopharyngeal and wound swabs, sputum, vomitus, skin wipes, wound bandages, and clothing articles (particularly shoes) may be collected for radionuclide analysis and counts. Collection of urine and feces for 24–72 hours may assist in estimation of an internal dose. Serum levels of radioactive materials are not generally available or clinically useful.

3. **Other methods.** Chromosomal changes in lymphocytes are the most sensitive indication of exposures to as little as 10 rad; DNA fragments, dicentric rings, and deletions may be present. Exposure to 15 rad may cause oligospermia first seen about 45 days after the exposure.

B. Other useful laboratory studies include CBC (repeat every 6 hours), electrolytes, glucose, BUN, creatinine, and urinalysis. Immediately draw lymphocytes for human leukocyte antigen (HLA) typing in case bone marrow transplant is required later.

V. Treatment. For expert assistance in evaluation and treatment of victims and in on-scene management, immediately contact the **Radiation Emergency Assistance Center & Training Site (REAC/TS): telephone (865) 576-3131 or (865) 481-1000**. REAC/TS is operated for the US Department of Energy (DOE) by the Oak Ridge Associated Universities, and assistance is available 24 hours a day. Also contact the local state agency responsible for radiation safety.

A. Emergency and supportive measures. Depending on the risk to rescuers, treatment of serious medical problems takes precedence over radiologic concerns. If there is a potential for contamination of rescuers and equipment, appropriate radiation response protocols should be implemented, and rescuers should wear protective clothing and respirators. **Note:** If the exposure was to electromagnetic radiation only, the victim is not contaminating and does not pose a risk to downstream personnel.

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).

2. Treat coma (see p 19) and seizures (p 22) if they occur.
 3. Replace fluid losses from gastroenteritis with intravenous crystalloid solutions (see p 16).
 4. Treat leukopenia and resulting infections as needed. Immunosuppressed patients require reverse isolation and appropriate broad-spectrum antibiotic therapy. Bone marrow stimulants may help selected patients.
- B. Specific drugs and antidotes.** Chelating agents or pharmacologic blocking drugs may be useful in some cases of ingestion or inhalation of certain biologically active radioactive materials, if they are given before or shortly after exposure (Table II-50). Contact REAC/TS (see above) for specific advice on use of these agents.
- C. Decontamination (p 46)**
1. **Exposure to particle-emitting solids or liquids.** *The victim is potentially highly contaminating to rescuers, transport vehicles, and attending health personnel.*
 - a. Remove victims from exposure, and if their conditions permit, remove all contaminated clothing and wash the victims with soap and water.
 - b. All clothing and cleansing water must be saved, evaluated for radioactivity, and properly disposed of.
 - c. Rescuers should wear protective clothing and respiratory gear to avoid contamination. At the hospital, measures must be taken to prevent contamination of facilities and personnel (see Section IV, pp 510 and 515).
 - d. Induce vomiting or perform gastric lavage (see p 48) if radioactive material has been ingested. Administer activated charcoal (see p 51), although its effectiveness is unknown. Certain other adsorbent materials may also be effective (see Table II-50).

TABLE II-50. CHELATING AND BLOCKING AGENTS FOR SELECTED RADIATION EXPOSURES^a

Radionuclide	Chelating or Blocking Agents
Cesium-137	Prussian blue (ferric hexacyanoferrate) adsorbs cesium in the GI tract, and may also enhance elimination. Dose: 500 mg PO 6 times daily in 100–200 mL of water.
Iodine-131	Potassium iodide dilutes radioactive iodine and blocks thyroid iodine uptake. Dose: 300 mg PO immediately, then 130 mg PO daily. (see p 456). Perchlorate, 200 mg PO, then 100 mg every 5 h, has also been recommended.
Plutonium-239	DTPA (see p 439): chelator. Dose: 1 g in 250 mL D5W IV over 30–60 min daily. Wounds: Irrigate with 1 g DTPA in 250 mL water. EDTA (see p 440) may also be effective if DTPA is not immediately available. Aluminum-containing antacids may bind plutonium in GI tract.
Strontium-90	Alginate or aluminum hydroxide-containing antacids may reduce intestinal absorption of strontium. Dose: 10 g, then 1 g 4 times daily. Barium sulfate may also reduce Sr absorption. Dose: 100 g in 250 mL water PO. Calcium gluconate may dilute the effect of strontium. Dose: 2 g in 500 mL PO or IV. Ammonium chloride is a demineralizing agent. Dose: 3 g PO 3 times daily.
Tritium	Forced fluids, diuretics, (?) hemodialysis. Water dilutes tritium, enhances urinary excretion.
Uranium-233, -235, -238	Sodium bicarbonate forms a carbonate complex with uranyl ion, which is then eliminated in the urine. Dose: 100 mEq in 500 mL D5W by slow constant IV infusion. Aluminum-containing antacids may help prevent uranium absorption.

^aReferences: Bhattacharyya ANL et al: Methods of treatment. Pages 27–36 in: *Radiation Protection Dosimetry*. Gerber GB, Thomas RG (editors). Vol. 41, No. 1 (1992); and Ricks RC: *Hospital Emergency Department Management of Radiation Accidents*. Oak Ridge Associated Universities, 1984.

- e. Contact REAC/TS (see above) and the state radiologic health department for further advice. In some exposures, unusually aggressive steps may be needed (eg, lung lavage for significant inhalation of plutonium).
- 2. **Electromagnetic radiation exposure.** *The patient is not radioactive and does not pose a contamination threat.* There is no need for decontamination once the patient has been removed from the source of exposure, unless electromagnetic radiation emitter fragments are embedded in body tissues.
- D. **Enhanced elimination.** Chelating agents and forced diuresis may be useful for certain exposures (see Table II-50).

► SALICYLATES

Susan Kim, PharmD

Salicylates are widely used for their analgesic and anti-inflammatory properties. They are found in a variety of prescription and over-the-counter analgesics, cold preparations, and topical keratolytic products (methyl salicylate), and even Pepto-Bismol (bismuth subsalicylate). Before the introduction of child-resistant containers, aspirin overdose was one of the leading causes of accidental death in children. Two distinct syndromes of intoxication may occur, depending on whether the exposure is **acute** or **chronic**.

I. Mechanism of toxicity. Salicylates have a variety of toxic effects.

- A. Central stimulation of the respiratory center results in hyperventilation, leading to respiratory alkalosis. Secondary consequences from hyperventilation include dehydration and compensatory metabolic acidosis.
- B. Intracellular effects include uncoupling of oxidative phosphorylation and interruption of glucose and fatty acid metabolism, which contribute to metabolic acidosis.
- C. The mechanism by which cerebral and pulmonary edema occurs is not known but may be related to an alteration in capillary integrity.
- D. Salicylates alter platelet function and may also prolong the prothrombin time.
- E. **Pharmacokinetics.** Acetylsalicylic acid is well absorbed from the stomach and small intestine. Large tablet masses and enteric-coated products may dramatically delay absorption (hours to days). The volume of distribution of salicylate is about 0.1–0.3 L/kg, but this can be increased by acidemia, which enhances movement of the drug into cells. Elimination is mostly by hepatic metabolism at therapeutic doses, but renal excretion becomes important with overdose. The elimination half-life is normally 2–4.5 hours but as long as 18–36 hours after overdose. Renal elimination is dependent on urine pH. See also Table II-59 (p 381).

II. Toxic dose. The average therapeutic single dose is 10 mg/kg, and the usual daily therapeutic dose is 40–60 mg/kg/day. Each tablet of aspirin contains 325–650 mg of acetylsalicylic acid. One teaspoon of concentrated **oil of wintergreen** contains 5 g of methyl salicylate, equivalent to about 7.5 g of aspirin.

- A. **Acute ingestion** of 150–200 mg/kg will produce mild intoxication; severe intoxication is likely after acute ingestion of 300–500 mg/kg.
- B. **Chronic intoxication** may occur with ingestion of more than 100 mg/kg/day for 2 or more days.

III. Clinical presentation. Patients may become intoxicated after an acute accidental or suicidal overdose or as a result of chronic repeated overmedication for several days.

A. Acute ingestion. Vomiting occurs shortly after ingestion, followed by hyperpnea, tinnitus, and lethargy. Mixed respiratory alkalemia and metabolic acidosis are apparent when arterial blood gases are determined. With severe intoxication, coma, seizures, hypoglycemia, hyperthermia, and pulmonary edema may occur. Death is caused by central nervous system failure and cardiovascular collapse.

B. Chronic intoxication. Victims are usually young children or confused elderly. The diagnosis is often overlooked because the presentation is nonspecific; confusion, dehydration, and metabolic acidosis are often attributed to sepsis, pneumonia, or gastroenteritis. However, morbidity and mortality rates are much higher than after acute overdose. Cerebral and pulmonary edema are more common than with acute intoxication, and severe poisoning occurs at lower salicylate levels.

IV. Diagnosis is not difficult if there is a history of acute ingestion, accompanied by typical signs and symptoms. In the absence of a history of overdose, diagnosis is suggested by the characteristic arterial blood gases, which reveal a mixed respiratory alkalemia and metabolic acidosis.

A. Specific levels. Obtain stat and serial serum salicylate concentrations. Systemic acidemia increases brain salicylate concentrations, worsening toxicity.

1. Acute ingestion. Serum levels greater than 90–100 mg/dL (900–1000 mg/L, or 6.6–7.3 mmol/L) are usually associated with severe toxicity. Single determinations are **not** sufficient because of the possibility of prolonged or delayed absorption from sustained-release tablets or a tablet mass or bezoar (especially after massive ingestion). Most toxicologists no longer use the Done Nomogram to estimate toxicity.

2. Chronic intoxication. Symptoms correlate poorly with serum levels, and the Done Nomogram cannot be used to predict toxicity. Chronic therapeutic concentrations in arthritis patients range from 100 to 300 mg/L (10–30 mg/dL). A level greater than 600 mg/L (60 mg/dL) accompanied by acidosis and altered mental status is considered very serious.

B. Other useful laboratory studies include electrolytes (anion gap calculation), glucose, BUN, creatinine, prothrombin time (PT), arterial blood gases, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). **Warning:** Ensure adequate ventilation to prevent respiratory acidosis, and do not allow controlled mechanical ventilation to interfere with the patient's need for compensatory efforts to maintain the serum pH. Administer supplemental oxygen. Obtain serial arterial blood gases and chest x-rays to observe for pulmonary edema (more common with chronic or severe intoxication).
2. Treat coma (see p 19), seizures (p 22), pulmonary edema (p 7), and hyperthermia (p 21) if they occur.
3. Treat metabolic acidosis with intravenous sodium bicarbonate (see p 419). Do **not** allow the serum pH to fall below 7.4.
4. Replace fluid and electrolyte deficits caused by vomiting and hyperventilation with intravenous crystalloid solutions. Be cautious with fluid therapy, because excessive fluid administration may contribute to pulmonary edema.
5. Administer supplemental glucose, and treat hypoglycemia (see p 34) if it occurs.
6. Monitor asymptomatic patients for a minimum of 6 hours (longer if an enteric-coated preparation or a massive overdose has been ingested and there is suspicion of a tablet bezoar). Admit symptomatic patients to an intensive care unit.

- B. Specific drugs and antidotes.** There is no specific antidote for salicylate intoxication. **Sodium bicarbonate** is frequently given both to prevent acidemia and to promote salicylate elimination by the kidneys (see D, below).
- C. Decontamination** (see p 47). Decontamination is not necessary for patients with *chronic* intoxication.
- 1. Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 - 2. Hospital.** Administer activated charcoal orally or by gastric tube. Gastric lavage is not necessary after small ingestions (ie, <300 mg/kg) if activated charcoal is given promptly.
 - 3. Note:** With very large ingestions of salicylate (eg, 30–60 g), very large doses of activated charcoal (300–600 g) are theoretically necessary to adsorb all the salicylate and prevent desorption. In such cases, the charcoal may be given in several 25- to 50-g doses at 3- to 5-hour intervals. Charcoal should be continued until the serum salicylate levels are clearly falling. Whole-bowel irrigation (see p 52) may help move the pills and charcoal through the intestinal tract.
- D. Enhanced elimination** (see p 54)
- 1. Urinary alkalization** is effective in enhancing urinary excretion of salicylate, although often difficult to achieve in dehydrated or critically ill patients.
 - a.** Add 100 mEq of sodium bicarbonate to 1 L of 5% dextrose in quarter normal saline, and infuse intravenously at 200 mL/h (3–4 mL/kg/h). If the patient is dehydrated, start with a bolus of 10–20 mL/kg. Fluid and bicarbonate administration is potentially dangerous in patients at high risk for pulmonary edema (eg, chronic intoxication).
 - b.** Unless renal failure is present, also add potassium, 30–40 mEq, to each liter of intravenous fluids (potassium depletion inhibits alkalization).
 - c.** Alkalemia is not a contraindication to bicarbonate therapy, considering that patients often have a significant base deficit in spite of the elevated serum pH.
 - 2. Hemodialysis** is very effective in rapidly removing salicylate and correcting acid-base and fluid abnormalities. Indications for urgent hemodialysis are as follows:
 - a.** Patients with acute ingestion and serum levels higher than 1000 mg/L (100 mg/dL) with severe acidosis and other manifestations of intoxication.
 - b.** Patients with chronic intoxication with serum levels higher than 600 mg/L (60 mg/dL) accompanied by acidosis, confusion, or lethargy, especially if the patient is elderly or debilitated.
 - c.** Any patient with severe manifestations of intoxication.
 - 3. Hemoperfusion** is also very effective but does not correct acid-base or fluid disturbances.
 - 4. Repeat-dose activated charcoal** therapy effectively reduces the serum salicylate half-life, but it is not as rapidly effective as dialysis, and frequent stooling may contribute to dehydration and electrolyte disturbances.
 - 5. Continuous venovenous hemodiafiltration** was reported to be effective in two cases, but there is insufficient information about clearance rates to recommend this procedure.

Wrathall G et al: Three case reports of the use of haemodiafiltration in the treatment of salicylate overdose. *Hum Exp Toxicol* 2001 Sep;20(9):491–495. [PMID: 11776412] (Reduction in serum levels from 8.5 to 3.5 mmol/L over 3 hours in one case, and from 6.2 to 4 mmol/L over 4 hours in another. The third case had only a modest decline from an initial level of 3 mmol/L.)

Dargan PI: An evidence-based flowchart to guide the management of acute salicylate (aspirin) overdose. *Emerg Med J* 2002;19(3):206–209. [PMID: 11971828] (Excellent and succinct review of salicylate poisoning management.)

► SCORPIONS

Richard F. Clark, MD

The order Scorpionida contains several families, genera, and species of scorpions. All have paired venom glands in a bulbous segment called the telson, located just anterior to a stinger on the end of the six terminal segments of the abdomen (often called a tail). The only dangerous species in the United States is the *Centruroides exilicauda* (formerly *C. sculpturatus*), also known as the bark scorpion. The most serious envenomations are usually reported in children under age 10 years. This scorpion is found primarily in the arid southwestern United States but has been found as a stowaway in cargo as far north as Michigan. Other dangerous scorpions are found in Mexico (*Centruroides* species), Brazil (*Tityus* species), India (*Buthus* species), the Middle East, and north Africa and the eastern Mediterranean (*Leiurus* and *Androctonus* species).

- I. **Mechanism of toxicity.** The scorpion grasps its prey with its anterior pincers, arches its pseudoabdomen, and stabs with the stinger. Stings also result from stepping on the stinger. The venom of *C. exilicauda* contains numerous digestive enzymes (eg, hyaluronidase and phospholipase) and several neurotoxins. Alteration in sodium channel flow results in excessive stimulation at neuromuscular junctions and the autonomic nervous system.
- II. **Toxic dose.** Variable amounts of venom from none to the complete contents of the telson may be ejected through the stinger.
- III. **Clinical presentation**
 - A. **Common scorpion stings.** Most stings result only in local, immediate, burning pain. Some local tissue inflammation and occasionally local paresthesias may occur. Symptoms usually resolve within several hours. This represents the typical scorpion sting seen in the United States.
 - B. **Dangerous scorpion stings.** In some victims, especially children under age 10 years, systemic symptoms occur, including weakness, restlessness, diaphoresis, diplopia, nystagmus, roving eye movements, hyperexcitability, muscle fasciculations, opisthotonus, priapism, salivation, slurred speech, hypertension, tachycardia, and, rarely, convulsions, paralysis, and respiratory arrest. Envenomations by *Tityus*, *Buthus*, *Androctonus*, and *Leiurus* species have caused pulmonary edema, cardiovascular collapse, and death, as well as coagulopathies, disseminated intravascular coagulation, pancreatitis, and renal failure with hemoglobinuria and jaundice. In nonfatal cases, recovery usually occurs within 12–36 hours.
- IV. **Diagnosis.** Either the patient saw the scorpion, or the clinician must recognize the symptoms. In the case of *Centruroides* stings, tapping on the sting site usually produces severe pain (“tap test”).
 - A. **Specific levels.** Body fluid toxin levels are not available.
 - B. No other useful laboratory studies are needed for minor envenomations. For severe envenomations, obtain CBC, electrolytes, glucose, BUN, creatinine, coagulation profile, and arterial blood gases.
- V. **Treatment.** The majority of scorpion stings in the United States, including those by *Centruroides*, can be managed with symptomatic care at home, consisting of oral analgesics and cool compresses or intermittent ice packs.
 - A. **Emergency and supportive measures**
 1. For severe envenomations, maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
 2. Treat hypertension (see p 17), tachycardia (p 12), and convulsions (p 22) if they occur.
 3. Do **not** overtreat with excessive sedation. One study reported benefit with a continuous infusion of midazolam in patients with severe *Centruroides* sting.
 4. Clean the wound and provide tetanus prophylaxis if indicated.
 5. Do **not** immerse the injured extremity in ice or perform local incision or suction.
 - B. **Specific drugs and antidotes.** An antivenom effective against severe *Centruroides* envenomations is available only in Arizona. However, production of

this antivenom has ceased, and supplies may be depleted by 2004. Specific antivenoms against other species may be available in other parts of the world, but are not approved in the United States.

- C. **Decontamination.** These procedures are not applicable.
- D. **Enhanced elimination.** These procedures are not applicable.

Abroug F et al: Serotherapy in scorpion envenomation: a randomised controlled trial. *Lancet* 1999;354(9182):906–909. [PMID: 10489950] (Prospective randomized study found no benefit of antivenom for scorpion stings in Tunisia.)

Gibly R et al: Continuous intravenous midazolam infusion for *Centruroides exilicauda* scorpion envenomation. *Ann Emerg Med* 1999;34(5):620–625. [PMID: 10533010] (Retrospective review of 33 patients with moderate or severe scorpion envenomation treated with midazolam infusion [median dose 0.10 mg/kg/h with a range of 0.06–1.29 mg/kg/h], with resolution of agitation and abnormal muscle activity.)

► **SEDATIVE-HYPNOTIC AGENTS**

Ben T. Tsutaoka, PharmD

Sedative-hypnotic agents are widely used for the treatment of anxiety and insomnia. As a group they are one of the most frequently prescribed medications. Barbiturates (see p 124), benzodiazepines (p 130), antihistamines (p 96), skeletal muscle relaxants (p 339), antidepressants (pp 88 and 90), and anticholinergic agents (p 84) are discussed elsewhere in this book. In this section (and Table II–51) are listed some of the less commonly used hypnotic agents.

- I. **Mechanism of toxicity.** The exact mechanism of action and the pharmacokinetics (see Table II–59, p 381) vary for each agent. The major toxic effect that causes serious poisoning or death is central nervous system depression resulting in coma, respiratory arrest, and pulmonary aspiration of gastric contents.
- II. **Toxic dose.** The toxic dose varies considerably between drugs and also depends largely on individual tolerance and the presence of other drugs such as alcohol. For most of these drugs, ingestion of 3–5 times the usual hypnotic dose results in coma. However, co-ingestion of alcohol or other drugs may cause

TABLE II–51. COMMON SEDATIVE-HYPNOTIC AGENTS^a

Drug	Usual Adult Oral Hypnotic Dose (mg)	Approximate Lethal Dose (g)	Toxic Concentration (mg/L)	Usual Half-Life ^b (h)
Buspirone	5–20	Unknown	—	2–4
Chloral hydrate ^c	500–1000	5–10	> 20 ^c	8–11 ^d
Ethchlorvynol	500–1000	5–10	> 10	10–20
Glutethimide	250–500	10–20	> 10	10–12
Meprobamate	600–1200	10–20	> 60	10–11
Methaqualone	150–250	3–8	> 5	20–60
Methypylon	200–400	5–10	> 10	7–11
Paraldehyde	5–10 mL	25 mL	> 200	6–7

^aSee also anticholinergic agents (p 84), antihistamines (p 96), barbiturates (p 124), benzodiazepines (p 130), and skeletal muscle relaxants (p 339).

^bHalf-life in overdose may be considerably longer.

^cToxic concentration is measured as the metabolite trichloroethanol.

^dHalf-life of the metabolite trichloroethanol.

coma after smaller ingestions, while individuals chronically using large doses of these drugs may tolerate much higher acute doses.

III. Clinical presentation. Overdose with any of these drugs may cause drowsiness, ataxia, nystagmus, stupor, coma, and respiratory arrest. Deep coma may result in absent reflexes, fixed pupils, and depressed or absent electroencephalographic (EEG) activity. Hypothermia is common. Most agents also slow gastric motility and decrease muscle tone. Hypotension with a large overdose is caused primarily by depression of cardiac contractility and, to a lesser extent, loss of venous tone.

A. Chloral hydrate is metabolized to trichloroethanol, which also has CNS-depressant activity. Trichloroethanol may also sensitize the myocardium to the effects of catecholamines, resulting in cardiac arrhythmias.

B. Buspirone may cause nausea, vomiting, drowsiness, and miosis. There are no reported deaths.

C. Ethchlorvynol has a pungent odor sometimes described as pear-like, and gastric fluid often has a pink or green color depending on the capsule form (200- and 500-mg capsules are red; 750-mg capsules are green).

D. Glutethimide often produces mydriasis (dilated pupils) and other anticholinergic side effects, and patients may exhibit prolonged and cyclic or fluctuating coma. It is sometimes taken in combination with codeine ("loads"), which may produce opioid effects.

E. Meprobamate has been reported to form tablet concretions in large overdoses, occasionally requiring surgical removal. Hypotension is more common with this agent than with other sedative-hypnotics. Meprobamate is the metabolite of skeletal muscle relaxant carisoprodol (see p 339).

F. Methaqualone is unusual among sedative-hypnotic agents in frequently causing muscular hypertonicity, clonus, and hyperreflexia.

IV. Diagnosis is usually based on a history of ingestion, because clinical manifestations are fairly nonspecific. Hypothermia and deep coma may cause the patient to appear dead; thus, careful evaluation should precede the diagnosis of brain death. Chloral hydrate is radiopaque and may be visible on plain abdominal x-rays.

A. Specific levels and qualitative urine screening are usually available through commercial toxicology laboratories.

1. Drug levels do not always correlate with severity of intoxication, especially in patients who have tolerance to the drug or who have also ingested other drugs or alcohol. In addition, early after ingestion blood levels may not reflect brain concentrations.

2. Some agents (chloral hydrate and glutethimide) have active metabolites, levels of which may correlate better with the state of intoxication.

B. Other useful laboratory studies include electrolytes, glucose, serum ethanol, BUN, creatinine, arterial blood gases, ECG, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.

2. Treat coma (see p 19), hypothermia (p 20), hypotension (p 16), and pulmonary edema (p 7) if they occur.

3. Monitor patients for at least 6 hours after ingestion, because delayed absorption may occur. Patients with **chloral hydrate** ingestion should be monitored at least 18–24 hours because of the risk of cardiac arrhythmias. Tachyarrhythmias caused by myocardial sensitization may be treated with **propranolol** (see p 496), 1–2 mg IV, or **esmolol** (see p 443), 0.025–0.1 mg/kg/min IV.

B. Specific drugs and antidotes. Flumazenil (see p 446) is a specific antagonist of benzodiazepine receptors. It does not appear to cross-react with other sedative agents.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of the risk of lethargy and coma.

2. Hospital. Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly; however, consider gastric lavage for massive ingestions.

D. Enhanced elimination. Because of extensive tissue distribution, dialysis and hemoperfusion are not very effective for most of the drugs in this group.

1. Repeat-dose charcoal may enhance elimination of glutethimide (which undergoes enterohepatic recirculation) and meprobamate, although no studies have been performed to document clinical effectiveness.
2. Meprobamate has a relatively small volume of distribution (0.7 L/kg), and hemoperfusion may be useful for deep coma complicated by intractable hypotension.
3. Resin hemoperfusion has been reported to be partially effective for ethchlorvynol overdose.

Zahedi A et al: Successful treatment of chloral hydrate cardiac toxicity with propranolol. *Am J Emerg Med* 1999;17(5):490–491. [PMID: 10496517] (Case report of chloral hydrate overdose complicated by ventricular arrhythmias controlled with propranolol.)

► SELENIUM

Richard J. Geller, MD, MPH

Selenium (element 34) belongs to column VIa of the periodic table of the elements, and shares chemical properties with sulfur and tellurium. It exists in four natural oxidation states, and is found in a variety of compounds capable of causing human poisoning. Table II–52 describes the chemistry of selenium compounds. Selenium is an essential trace element in the human diet, and exposures may occur through use of dietary supplements as well as via exposure to industrial compounds. Serious acute poisoning is most commonly reported from ingestion of selenious acid in gun bluing (coating) solutions. Illness caused by chronic exposure to selenium is uncommon, but is seen in regions with high selenium content in food. Industries using selenium compounds include ceramics, electronics, glass, rubber, and metallurgy. Selenium dioxide is the most commonly used compound industrially. Selenium production is largely as a by-product of copper refining.

I. Mechanism of toxicity. Precise cellular toxopathology is poorly understood. Animal studies implicate mechanisms involving the formation of superoxide and hydroxyl anions as well as hydrogen peroxide. Mechanistic knowledge makes no contribution to treatment currently. A garlic breath odor observed in various selenium poisonings is due to in vivo creation of dimethylselenium.

II. Toxic dose

A. Ingestion. Little is known about the oral toxic dose because there are few reports of poisoning.

1. Acute overdose. The oral mean lethal dose (MLD) of selenite salts in the dog is about 4 mg/kg. Ingestion of 1–5 mg/kg sodium selenite in five adults caused moderate reversible toxicity. Ingestion of as little as 15 mL of gun bluing solution (2% selenious acid) has been fatal.

2. Chronic ingestion. The recommended nutritional daily intake is 50–200 mcg. The drinking water maximum contaminant level (MCL) is 10 mcg/L. Chronic ingestion of 850 mcg/day has been associated with toxicity.

B. Inhalation. The recommended threshold limit value (TLV) for occupational exposure to elemental selenium, as well as selenium compounds in general, has been set at 0.2 mg/m³. The exposure levels considered immediately dangerous to life or health (IDLH) are listed in Table II–52.

III. Clinical presentation

A. Acute ingestion of selenious acid causes upper GI corrosive injury, vomiting and diarrhea, hypersalivation, and a garlic odor on the breath, with rapid deterioration of mental status with restlessness progressing to coma, hypotension from myocardial depression and decreased vascular resistance,

TABLE II-52. SELENIUM COMPOUNDS

Compound (Synonyms)	Physical Properties	Toxic Dose or Air Concentration ^a
Elemental selenium CASRN 7782-49-2	Amorphous or crystalline, red to gray solid	PEL 0.2 mg/m ³ IDLH 1 mg/m ³
Hydrogen selenide (selenium hydride) CASRN 7783-07-5	Odiferous colorless gas	PEL 0.05 ppm IDLH 1 ppm
Sodium selenide CASRN 1313-85-5	Red to white powder	PEL 0.2 mg/m ³ (as Se)
Selenious acid (hydrogen selenite) CASRN 7783-00-8	White powder encountered as 2% solution in gun bluing	Ingestion of as little as 15 mL of a 2% solution was reported fatal in a child.
Sodium selenite (selenium trioxide) CASRN 10102-18-8	White powder	Mean lethal dose of selenite salts in dogs 4 mg/kg. Human ingestion of 1–5 mg/kg sodium selenite caused moderate toxicity.
Selenium oxide (selenium dioxide) CASRN 7446-08-4	White crystal or powder	PEL 0.2 mg/m ³ (as Se)
Sodium selenate CASRN 13410-01-0	White crystals	PEL 0.2 mg/m ³ (as Se)
Selenic acid CASRN 7783-08-6	White solid	PEL 0.2 mg/m ³ (as Se)
Selenium hexafluoride (selenium fluoride) CASRN 7783-79-1	Colorless gas	PEL 0.05 ppm IDLH 2 ppm

^aPEL = OSHA-regulated permissible exposure limit for occupational exposure, as an 8-hour time weighted average (TWA); IDLH = level considered immediately dangerous to life or health (NIOSH).

respiratory insufficiency, and death. Suicidal ingestion of an unknown amount of **selenium dioxide** has been fatal. Ingestions of **sodium selenate** have produced gastroenteritis with garlic breath, and T-wave inversion on the ECG. Five patients ingesting large amounts of **sodium selenite** developed vomiting, diarrhea, chills, and tremor, but survived.

B. Chronic ingestion of elemental selenium, sodium selenite, sodium selenate, or selenium dioxide may cause pallor, stomach disorders, nervousness, metallic taste, and garlic breath.

C. Acute inhalation of hydrogen selenide produces dyspnea, abdominal cramps, and diarrhea. Inhalation of **selenium hexafluoride** produces severe corrosive injury and systemic toxicity from acids of selenium plus fluoride ion toxicity. **Selenium salt** inhalation causes dyspnea and skin and mucous membrane irritation.

IV. Diagnosis is difficult without a history of exposure. Acute severe gastroenteritis with garlic breath odor and hypotension may suggest selenious acid poisoning, but these findings are not specific.

A. Specific levels are not generally available. Selenium can be measured in the blood, hair, and urine. Whole-blood levels remain elevated longer than serum levels (which are typically 40–60% lower) and may reflect long-term exposure.

1. On a normal diet, whole-blood selenium levels range from 0.1 to 0.2 mg/L. One patient with chronic intoxication after ingestion of 31 mg/day had a whole-blood selenium level of 0.53 mg/L.
2. Average hair levels are up to 0.5 ppm. The relationship between hair and tissue concentrations is not well understood. The utility of hair testing is complicated by the widespread use of selenium in shampoos.

- Both whole-blood and urinary concentrations reflect dietary intake. Over-exposure should be considered when blood selenium levels exceed 0.4 mg/L or urinary excretion exceeds 600–1000 mcg/day.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver transaminases, and ECG. After inhalation exposure, obtain arterial blood gases or oximetry and chest x-ray.

V. Treatment

A. Emergency and supportive measures

- Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
- Treat coma (see p 19), convulsions (p 22), bronchospasm (p 8), hypotension (p 16), and pulmonary edema (p 7) if they occur. Since hypotension is often multifactorial, evaluate and optimize volume status, peripheral vascular resistance, and myocardial contractility.
- Observe for at least 6 hours after exposure.
- After ingestion of selenious acid, consider endoscopy to rule out esophageal or gastric corrosive injury.

B. Specific drugs and antidotes. There is no specific antidote. The value of suggested therapies such as chelation, vitamin C, and *N*-acetylcysteine is not established.

C. Decontamination (see p 46)

- Inhalation.** Immediately remove the victim from exposure and give supplemental oxygen if available.
- Skin and eyes.** Remove contaminated clothing and wash exposed skin with soap and copious water. Irrigate exposed eyes with copious tepid water or saline.
- Ingestion** (see p 46)
 - Prehospital.** Administer activated charcoal if available. Do **not** administer ipecac or induce vomiting because of risk of corrosive injury and potential for abrupt onset of seizures.
 - Hospital.** Ingestion of elemental selenium or selenium salts does not usually benefit from GI decontamination. Being mindful of the risk of severe corrosive GI injury, gastric lavage plus activated charcoal may be of value for ingestions of selenious acid seen within 1 hour.
 - In vitro experiments indicate that **vitamin C** can reduce selenium salts to elemental selenium, which is poorly absorbed. Its use has not been studied in vivo, but oral or nasogastric administration of several grams of ascorbic acid has been recommended.

D. Enhanced elimination. There is no known role for any enhanced removal procedure.

Barceloux DG: Selenium. *J Toxicol Clin Toxicol* 1999;37(2):145–172. [PMID:10382553] (Encyclopedic review of selenium.)

Quadrani DA et al: A fatal case of gun blue ingestion in a toddler. *Vet Hum Toxicol* 2000;42(2):96–98. [PMID: 10750175] (Death in a 22-month-old boy who ingested up to 15 mL of Gun Blue solution.)

► SKELETAL MUSCLE RELAXANTS

Susan Kim, PharmD

Various drugs have been used to treat muscle spasm. Most compounds in this group act as simple sedative-hypnotic agents and produce skeletal muscle relaxation indirectly. The drugs commonly used as skeletal muscle relaxants are listed in Table II–53. Carisoprodol (Soma™) and baclofen have been abused as recreational drugs.

I. Mechanism of toxicity

A. Central nervous system. Most of these drugs cause generalized CNS depression.

TABLE II-53. COMMON SKELETAL MUSCLE RELAXANTS

Drug	Usual Half-Life	Usual Daily Adult Dose (mg)
Baclofen	2.5–4	40–80
Carisoprodol ^a	1.5–8	800–1600
Chlorzoxazone	1	1500–3000
Cyclobenzaprine	24–72	30–60
Methocarbamol	1–2	4000–4500
Orphenadrine	14–16	200

^aMetabolized to meprobamate (see p 335).

1. **Cyclobenzaprine** and **orphenadrine** have anticholinergic side effects.
2. **Baclofen** is an agonist at the GABA(B) receptor and can produce profound CNS and respiratory depression as well as paradoxical muscle hypertonicity and seizure-like activity. Hallucinations, seizures, and hyperthermia have occurred after abrupt withdrawal from baclofen.
3. Spastic encephalopathy is also common with **carisoprodol** overdose.
4. Tizanidine, a centrally acting alpha-2 agonist, has effects similar to clonidine (see p 169)
- B. **Cardiovascular effects.** Hypotension may occur after overdose. **Baclofen** has caused bradycardia in up to 30% of ingestions. Massive **orphenadrine** ingestions have caused supraventricular and ventricular tachycardia.
- C. **Pharmacokinetics** vary with the drug. Absorption may be delayed because of anticholinergic effects. See also Table II-59, p 381.
- II. **Toxic dose.** The toxic dose varies considerably between drugs, depends largely on individual tolerance, and can be influenced by the presence of other drugs such as ethanol. For most of these drugs, ingestion of more than 3–5 times the usual therapeutic dose may cause stupor or coma. Death was reported in a 4-year-old who ingested approximately 3500 mg of carisoprodol.
- III. **Clinical presentation.** Onset of CNS depression is usually seen within 30–120 minutes of ingestion. Lethargy, slurred speech, ataxia, coma, and respiratory arrest may occur. Larger ingestions, especially when combined with alcohol, can produce unresponsive coma.
 - A. **Carisoprodol** may cause hyperreflexia, opisthotonus, and increased muscle tone.
 - B. **Cyclobenzaprine** and **orphenadrine** can produce anticholinergic findings, such as tachycardia, dilated pupils, and delirium. Despite its structural similarity to tricyclic antidepressants, cyclobenzaprine has not been reported to cause quinidine-like cardiotoxicity
 - C. **Baclofen** overdose causes coma, respiratory depression, occasional bradycardia, and paradoxical seizure-like activity. Onset is rapid but may last 12–48 hours.
 - D. **Tizanidine** is similar to clonidine (see p 169); in addition, SA and AV nodal dysfunction was reported after an overdose.
- IV. **Diagnosis** is usually based on the history of ingestion and findings of CNS depression, often accompanied by muscle twitching or hyperreflexia. The differential diagnosis should include other sedative-hypnotic agents (see p 335).
 - A. **Specific levels.** Many of these drugs can be detected on comprehensive urine toxicology screening. Quantitative drug levels do not always correlate with severity of intoxication, especially in patients who have tolerance to the drug or who have also ingested other drugs or alcohol. In addition, early after ingestion blood levels may not reflect brain concentrations.

B. Other useful laboratory studies include electrolytes, glucose, serum ethanol, BUN, creatinine, arterial blood gases, and chest x-ray.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
2. Treat coma (see p 19), hypothermia (p 20), hypotension (p 16), and pulmonary edema (p 7) if they occur. Hypotension usually responds promptly to supine position and intravenous fluids.
3. Monitor patients for at least 6 hours after ingestion, because delayed absorption may occur.

B. Specific drugs and antidotes. There are no specific antidotes. Flumazenil (see p 446) is a specific antagonist of benzodiazepine receptors, and would not be expected to cross-react with skeletal muscle relaxants or other sedative agents. While physostigmine may reverse anticholinergic symptoms associated with cyclobenzaprine and orphenadrine overdose, it is not generally needed and may potentially cause seizures.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the risk of lethargy and coma.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly; however, consider gastric lavage for massive ingestions.

D. Enhanced elimination. Because of extensive tissue distribution, dialysis and hemoperfusion are not very effective for most of the drugs in this group. Repeat-dose charcoal may enhance elimination of meprobamate, although no studies have been performed to document this.

Ostermann ME et al: Coma mimicking brain death following baclofen overdose. *Intensive Care Med* 2000;26(8):1144–1146. [PMID: 11030173] (Full neurologic recovery in a patient with severe baclofen overdose presenting in deep coma with absent brainstem reflexes.)

Roth BA et al: Carisoprodol-induced myoclonic encephalopathy. *J Toxicol Clin Toxicol* 1998;36(6):609–612. [PMID: 9776967] (Coma accompanied by myoclonus in a man who ingested 35 g of carisoprodol, and had a serum level of 71 mg/L and metabolite meprobamate level of 26 mg/L.)

► SMOKE INHALATION

Kent R. Olson, MD

Smoke inhalation commonly occurs in fire victims and is associated with high morbidity and mortality. In addition to thermal injury, burning organic and inorganic materials can produce a very large number of different toxins, leading to chemical injury to the respiratory tract as well as systemic effects from absorption of poisons through the lungs. “Smoke bombs” do not release true smoke but can be hazardous because of irritant components, particularly zinc chloride.

I. Mechanism of toxicity. Smoke is a complex mixture of gases, fumes, and suspended particles. Injury may result from:

A. Thermal damage to the airway and tracheobronchial passages.

B. Irritant gases, vapors, and fumes that can damage the upper and lower respiratory tract (see p 213). Many common irritant substances are produced by thermal breakdown and combustion, including acrolein, hydrogen chloride, phosgene, and nitrogen oxides.

C. Asphyxia due to consumption of oxygen by the fire and production of carbon dioxide and other gases.

- D. Toxic systemic effects** of inhaled carbon monoxide, cyanide, and other systemic poisons. Cyanide is a common product of combustion of plastics, wool, and many other natural and synthetic polymers.
- II. Toxic dose.** The toxic dose varies depending on the intensity and duration of the exposure. Inhalation in a confined space with limited egress is typically associated with delivery of a greater toxic dose.
- III. Clinical presentation**
- A. Thermal and irritant effects** include singed nasal hairs, carbonaceous material in the nose and pharynx, cough, wheezing, and dyspnea. Stridor is an ominous finding that suggests imminent airway compromise due to swelling in and around the larynx. Pulmonary edema, pneumonitis, and adult respiratory distress syndrome (ARDS) may occur. Inhalation of steam is strongly associated with deep thermal injury but is not complicated by systemic toxicity.
- B. Asphyxia and systemic intoxicants** may cause dizziness, confusion, syncope, seizures and coma. In addition, carbon monoxide (see p 151), cyanide poisoning (p 177), and methemoglobinemia (p 261) have been documented in victims of smoke inhalation.
- IV. Diagnosis** should be suspected in any patient brought from a fire, especially with facial burns, singed nasal hairs, carbonaceous deposits in the upper airways or in the sputum, or dyspnea.
- A. Specific levels.** Carboxyhemoglobin, methemoglobin, and blood cyanide levels can be performed. Unfortunately, cyanide levels are not readily available with short turnaround time in most hospitals. Thus, the diagnosis may be empiric.
- B. Other useful laboratory studies** include arterial blood gases or oximetry, chest x-ray, spirometry, or peak expiratory flow measurement. Arterial blood gases, pulse oximetry, and chest x-ray may reveal early evidence of chemical pneumonitis or pulmonary edema. However, arterial blood gases and pulse oximetry are *not* reliable in patients with carbon monoxide poisoning or methemoglobinemia.
- V. Treatment**
- A. Emergency and supportive measures**
1. Immediately assess the airway; hoarseness or stridor suggests laryngeal edema, which may necessitate direct laryngoscopy and endotracheal intubation if sufficient swelling is present (see p 4). Assist ventilation if necessary (p 6).
 2. Administer high-flow supplemental oxygen by tight-fitting nonrebreather mask (see p 482).
 3. Treat bronchospasm with aerosolized bronchodilators (see p 8).
 4. Treat pulmonary edema if it occurs (see p 7).
- B. Specific drugs and antidotes**
1. **Carbon monoxide** poisoning. Provide 100% oxygen by mask or endotracheal tube. Consider hyperbaric oxygen (see p 482).
 2. **Cyanide** poisoning. Empiric antidotal therapy with **sodium thiosulfate** (see p 505) and (if available) **hydroxocobalamin** (p 453) is recommended for patients with altered mental status, hypotension, or acidosis. Use of sodium nitrite is discouraged because it may cause hypotension and aggravate methemoglobinemia.
 3. Treat **methemoglobinemia** with **methylene blue** (see p 466).
- C. Decontamination** (see p 47). Once the victim is removed from the smoke environment, further decontamination is not needed.
- D. Enhanced elimination.** Consider hyperbaric oxygen (see p 482) for carbon monoxide poisoning.

Alarie Y: Toxicity of fire smoke. *Crit Rev Toxicol* 2002;32(4):259–289. [PMID: 12184505] (Review.)

Chou KJ et al: Characteristics and outcome of children with carbon monoxide poisoning with and without smoke exposure referred for hyperbaric oxygen therapy. *Pediatr Emerg Care* 2000;16(3):151–155. [PMID: 10888449] (Children with smoke inhalation injury and carbon monoxide poisoning have a higher mortality rate than children with CO poisoning alone.)

► SNAKEBITE

Richard F. Clark, MD

Of the 14 families of snakes, 5 are poisonous (Table II–54). The annual incidence of snakebite in the United States is three to four bites per 100,000 population. Clinically significant morbidity occurs in less than 60%, and only a few deaths are reported each year. Rattlesnake bite is the most common snake envenomation in the United States, and the victim is often a young, intoxicated male who was teasing or trying to capture the snake. Snakes strike accurately to about one-third their body length, with a maximum striking distance of a few feet.

- I. **Mechanism of toxicity.** Snake venoms are complex mixtures of 50 or more components that function to immobilize, kill, and predigest prey. In human victims, these substances produce local “digestive” effects on tissues as well as hemotoxic, neurotoxic, and other systemic effects. The relative predominance of digestive, hemotoxic, or neurotoxic venom components depends on the species of the snake and geographic variables.
- II. **Toxic dose.** The potency of the venom and the amount of venom injected vary considerably. About 20% of all snake strikes are “dry” bites in which there is no envenomation.
- III. **Clinical presentation.** The most common snake envenomations in the United States are from rattlesnakes (Crotalidae). Bites from common North American Elapidae (eg, coral snakes) and Colubridae (eg, king snakes) are also discussed here. For information about bites from other exotic snakes, contact a regional poison control center ([800] 222-1222) for a specific consultation.
- A. **Crotalidae.** Fang marks may look like puncture wounds or lacerations, the latter resulting from a glancing blow by the snake or sudden movement by the victim. The fangs often penetrate only a few millimeters but occasionally enter

TABLE II–54. EXAMPLES OF POISONOUS SNAKES

Family and Genera	Common Name	Comments
Colubridae		
<i>Lampropeltis</i>	King snake	Human envenomation difficult because of small mouth and small fixed fangs in the rear of mouth. Larger African species may cause severe systemic coagulopathy.
<i>Heterodon</i>	Hognose	
<i>Coluber</i>	Racer	
<i>Dispholidus</i>	Boomslang	
Elapidae		
<i>Micrurus</i>	Coral snake	Human envenomation difficult because of small mouth and small fixed fangs in rear of mouth. Neurotoxicity usually predominates.
<i>Naja</i>	Cobra	
<i>Bungarus</i>	Krait	
<i>Dendroaspis</i>	Mamba	
Hydrophidae	Sea snakes	Also have small rear-located fangs.
Viperidae-subfamily Crotalidae		
<i>Crotalus</i>	Rattlesnake	Most common envenomation in USA. Long rotating fangs in the front of the mouth. Heat-sensing facial pits (hence the name “pit vipers”).
<i>Agkistrodon</i>	Copperhead, cottonmouth	
<i>Bothrops</i>	Fer-de-lance	
Viperidae-subfamily Viperinae		
<i>Bitis</i>	Puff adder, Gaboon viper	Long rotating fangs in the front of the mouth, but no heat-sensing facial pits.
<i>Cerastes</i>	Cleopatra’s asp	
<i>Echis</i>	Saw-scaled viper	

deeper tissue spaces or blood vessels. Signs and symptoms of toxicity are almost always apparent within 8–12 hours of envenomation.

1. **Local effects.** Within minutes of envenomation, stinging, burning pain begins. Progressive swelling, erythema, petechiae, ecchymosis, and hemorrhagic blebs may develop over the next several hours. The limb may swell to twice its normal size within the first few hours. Hypovolemic shock and local compartment syndrome may occur secondary to fluid and blood sequestration in injured areas.
2. **Systemic effects** may include nausea and vomiting, weakness, muscle fasciculations, diaphoresis, perioral and peripheral paresthesias, a metallic taste, thrombocytopenia, and coagulopathy. Circulating vasodilatory compounds may contribute to hypotension. Pulmonary edema and cardiovascular collapse have been reported.
3. **Mojave rattlesnake** (*Crotalus scutulatus*) bites deserve special consideration and caution, because neurologic signs and symptoms of envenomation may be delayed and there is often little swelling or evidence of tissue damage. The onset of muscle weakness, ptosis, and respiratory arrest may occur several hours after envenomation. Facial and laryngeal edema have also been reported.

B. Elapidae. Coral snake envenomation is rare because of the snake's small mouth and fangs. The snake must hold on and "chew" the extremity for several seconds or more to work its fangs into the skin.

1. **Local effects.** There is usually minimal swelling and inflammation around the fang marks. Local paresthesias may occur.
2. **Systemic effects.** Systemic symptoms usually occur within a few hours but may be delayed 12 hours or more. Nausea and vomiting, euphoria, confusion, diplopia, dysarthria, muscle fasciculations, generalized muscle weakness, and respiratory arrest may occur.

C. Colubridae. These small-mouthed rear-fanged snakes must also hang onto their victims and "chew" the venom into the skin before significant envenomation can occur.

1. **Local effects.** There is usually little local reaction other than mild pain and paresthesias, although swelling of the extremity may occur.
2. **Systemic effects.** The most serious effect of envenomation is systemic coagulopathy, which can be fatal, but is rare in all but a few African colubrids.

IV. Diagnosis. Correct diagnosis and treatment depend on proper identification of the offending snake, especially if more than one indigenous poisonous species or an exotic snake is involved.

A. Determine whether the bite was by an indigenous (wild) species or an exotic zoo animal or illegally imported pet. (The owner of an illegal pet snake may be reluctant to admit this for fear of fines or confiscation.) Envenomation occurring during the fall and winter months (October–March) when snakes usually hibernate is not likely to be caused by a wild species.

B. If the snake is available, attempt to have it identified by a herpetologist. **Caution:** Accidental envenomation may occur even after the snake is dead.

C. Specific levels. These tests are not applicable.

D. Other useful laboratory studies include CBC, platelet count, prothrombin time (PT), fibrin split products, fibrinogen, CPK, and urine dipstick for occult blood (positive with free myoglobin or hemoglobin). For severe envenomations with frank bleeding, hemolysis, or anticipated bleeding problems, obtain a blood type and screen early. If compromised respiratory function is suspected, closely monitor oximetry and arterial blood gases.

V. Treatment

A. Emergency and supportive measures. Regardless of the species, prepare for both local and systemic manifestations. Monitor patients closely for at least 6–8 hours after a typical crotalid bite and for at least 12–24 hours after *C. scutulatus* or an elapid bite.

1. Local effects

- a. **Monitor local swelling** at least hourly with measurements of limb girth, the presence and extent of local ecchymosis, and assessment of circulation.
- b. When indicated, obtain consultation with an experienced surgeon for management of serious wound complications. Do not perform fasciotomy unless compartment syndrome is documented with tissue compartment pressure monitoring.
- c. Provide tetanus prophylaxis if needed.
- d. Administer broad-spectrum antibiotics only if there are signs of infection.

2. Systemic effects

- a. **Monitor the victim for respiratory muscle weakness.** Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen.
- b. Treat bleeding complications with fresh-frozen plasma (and antivenin; see below). Treat hypotension with intravenous crystalloid fluids (see p 16), and rhabdomyolysis (p 27) with fluids and sodium bicarbonate.

B. Specific drugs and antidotes. For patients with documented envenomation, be prepared to administer specific **antivenom**. Virtually all local and systemic manifestations of envenomation improve after antivenom administration. **Caution:** Life-threatening anaphylactic reactions may occur with antivenom administration, even after a negative skin test.

1. For **rattlesnake** and other **Crotalidae** envenomations, the presence of fang marks, limb swelling, ecchymosis, and severe pain at the bite site are considered minimal indications for **Crotalidae antivenom** (see p 407). Progressive systemic manifestations such as generalized fasciculations, coagulopathy, and muscle weakness are indications for prompt and aggressive treatment. For a Mojave rattlesnake bite, the decision to administer antivenom is more difficult because there are few local signs of toxicity.
2. For **coral snake** envenomation, consult a regional poison control center ([800] 222-1222) or an experienced medical toxicologist to determine the advisability of **Micrurus fulvius antivenin** (see p 410). In general, if there is evidence of coagulopathy or neurologic toxicity, administer antivenin.
3. For **Colubridae** envenomations, there are no antivenins available.
4. For **other exotic snakes**, consult a regional poison control center ([800] 222-1222) for assistance in diagnosis, location of specific antivenin, and indications for administration.

C. Decontamination. First-aid measures are generally ineffective and may cause additional tissue damage.

1. Remain calm, remove the victim to at least 20 feet from the snake, wash the area with soap and water, and remove any constricting clothing or jewelry. Apply ice sparingly to the site (excessive ice application or immersion in ice water can lead to frostbite and aggravate tissue damage).
2. Loosely splint or immobilize the extremity near heart level. **Do not apply a tourniquet.**
3. Do **not** make cuts over the bite site.
4. If performed within 15 minutes, **suction** over the fang marks (ie, with a Sawyer extractor) may remove some venom but this should not delay transport to a hospital. Suction devices have not been demonstrated to improve outcome and some studies suggest that may increase tissue damage. Mouth suction of the wound is not advised.

D. Enhanced elimination. Dialysis, hemoperfusion, and charcoal administration are not applicable.

McKinney PE: Out-of-hospital and interhospital management of crotaline snakebite. *Ann Emerg Med* 2001;37(2):168–174. [PMID: 11174235] (Review of prehospital and interhospital care.)

► SPIDERS

Jeffrey R. Suchard, MD

Most of the more than 50,000 species of spiders in the United States possess poison glands connected to fangs in the large, paired, jawlike structures known as chelicerae. Fortunately, however, only a very few spiders have fangs long and tough enough to pierce human skin. In the United States, these include ***Latrodectus*** (black widow), ***Loxosceles*** (brown recluse spider), and ***tarantulas*** (a common name given to many large spiders), and a few others.

Latrodectus species (black widow) are ubiquitous in the continental United States, and the female can cause serious envenomations with rare fatalities. Black widows construct their chaotic webs in dark places, often near human habitation in garages, wood piles, outdoor toilets, and patio furniture. The spider has a body size of 1–2 cm and is characteristically shiny black with a red hourglass shape on the ventral abdomen. Related species or immature specimens may have brown, red, or orange markings or have irregular markings on a black body.

Loxosceles reclusa (the brown recluse spider) is found mainly in the central and southeastern United States (eg, Missouri, Kansas, Arkansas, and Tennessee). Rare individual specimens have been found in other areas, but these represent stow-aways on shipments from endemic areas. Other ***Loxosceles*** species may be found in the desert southwest, although they tend to cause less serious envenomations. The spider's nocturnal hunting habits and reclusive temperament result in infrequent contact with humans and bites are generally defensive in nature. The spider is 1–3 cm in length, light to dark brown in color, with a characteristic violin- or fiddle-shaped marking on the dorsum of the cephalothorax.

Tarantulas rarely cause significant envenomation but can produce a painful bite because of their large size. Tarantulas also bear urticating hairs that they can flick at predators and which cause intense mucosal irritation. People keeping pet tarantulas have developed ophthalmia nodosa when these hairs embed in their corneas, usually while cleaning their spiders' cages.

- I. **Mechanism of toxicity.** Spiders use their hollow fangs (chelicerae) to inject their venoms, which contain various protein and polypeptide toxins that are poorly characterized but appear to be designed to induce rapid paralysis of the insect victim and to aid in digestion.
 - A. ***Latrodectus*** (black widow) spider venom contains *alpha-latrotoxin*, which causes opening of nonspecific cation channels, leading to an increased influx of calcium and indiscriminate release of acetylcholine (at the motor endplate) and norepinephrine.
 - B. ***Loxosceles*** (brown spiders) venom contains a variety of digestive enzymes and sphingomyelinase D, which is cytotoxic, chemotactically attracts white blood cells to the bite site, and also has a role in producing systemic symptoms such as hemolysis.
- II. **Toxic dose.** Spider venoms are generally extremely potent toxins (far more potent than most snake venoms), but the delivered dose is extremely small. The size of the victim may be an important variable.
- III. **Clinical presentation.** Manifestations of envenomation are quite different depending on the species.
 - A. ***Latrodectus*** (black widow) inflicts a bite that can range from mild erythema to a target lesion with a central punctate site, central blanching, and an outer erythematous ring.
 1. The bite is often initially painful but may go unnoticed. It almost always becomes painful within 30–120 minutes. By 3–4 hours, painful cramping and

muscle fasciculations occur in the involved extremity. This cramping progresses toward the chest, back, or abdomen and can produce board-like rigidity, weakness, dyspnea, headache, and paresthesias. Black widow envenomation may mimic myocardial infarction or an acute surgical abdomen. Symptoms often persist for 1–2 days.

2. Additional common symptoms may include hypertension, regional diaphoresis, restlessness, nausea, vomiting, and tachycardia.
3. Other less common symptoms include leukocytosis, fever, delirium, arrhythmias, and paresthesias. Rarely, hypertensive crisis or respiratory arrest may occur after severe envenomation, mainly in very young or very old victims.

B. *Loxosceles* bites are best known for causing slowly healing skin ulcers, a syndrome often called “necrotic arachnidism.”

1. Envenomation usually produces a painful burning sensation at the bite site within 10 minutes, but can be delayed. Over the next 1–12 hours, a “bull’s-eye” lesion forms, consisting of a blanched ring enclosed by a ring of ecchymosis. The entire lesion can range from 1 to 5 cm in diameter. Over the next 24–72 hours, an indolent necrotic ulcer develops that may take a month or more to heal. However, in most cases necrosis is limited and healing occurs rapidly.
2. Systemic illness may occur in the first 24–48 hours and does not necessarily correlate with the severity of the ulcer. Systemic manifestations include fever, chills, malaise, nausea, and myalgias. Rarely, intravascular hemolysis and disseminated intravascular coagulopathy may occur.

C. Other spiders. Bites from most other spider species are of minimal clinical consequence. As with many arthropod bites, a self-limited local inflammatory reaction may occur, and any break in the skin may become secondarily infected. Bites from a few species can cause systemic symptoms (myalgias, arthralgias, headache, nausea, vomiting) or necrotic ulcers (eg, *Phidippus* spp and *Tegenaria agrestis*).

IV. Diagnosis is most commonly made based on the characteristic clinical presentation. Bite marks of all spiders but the tarantulas are usually too small to be easily visualized, and victims often do not recall feeling the bite or seeing the spider. Spiders (especially the brown recluse) have bad reputations far exceeding their actual danger to humans, and patients may ascribe a wide variety of skin lesions and other problems to spider bites. Many other arthropods and insects also produce small puncture wounds, pain, itching, redness, swelling, and even necrotic ulcers. Arthropods that seek blood meals from mammals are more likely to bite humans than spiders. Several other medical conditions can cause necrotic skin ulcers, including bacterial, viral, and fungal infections, and vascular, dermatologic, and even factitious disorders. Thus, any prospective diagnosis of “brown recluse spider bite” requires careful scrutiny. Unless the patient gives a reliable eyewitness history, brings the offending animal for identification (and not just any spider found around the home), or exhibits systemic manifestations clearly demonstrating spider envenomation, the evidence is circumstantial at best.

A. Specific levels. Serum toxin detection is used experimentally, but is not commercially available.

B. Other useful laboratory studies

1. ***Latrodectus*.** Electrolytes, calcium, glucose, CPK, and ECG (for chest pain).
2. ***Loxosceles*.** CBC, BUN, and creatinine. If hemolysis is suspected, haptoglobin and urine dipstick for occult blood (positive with free hemoglobin) are useful; repeat daily for 1–2 days.

V. Treatment

A. Emergency and supportive measures

1. General

- a. Cleanse the wound and apply cool compresses or intermittent ice packs. Treat infection if it occurs.
- b. Give tetanus prophylaxis if indicated.

2. *Latrodectus* envenomation

- a. Monitor victims for at least 6–8 hours. Because symptoms typically wax and wane, patients may appear to benefit from any therapy offered.
- b. Maintain an open airway and assist ventilation if necessary (see pp 1–7), and treat severe hypertension (p 17) if it occurs.

3. *Loxosceles* envenomation

- a. Do not excise or debride aggressively on initial evaluation.
- b. Admit patients with systemic symptoms and monitor for hemolysis, renal failure, and other complications.

B. Specific drugs and antidotes**1. *Latrodectus***

- a. Most patients will benefit from opiate analgesics such as **morphine** (see p 468) and often are admitted for 24–48 hours for pain control in serious cases.
- b. Muscle cramping has been treated with **intravenous calcium** (see p 424) or muscle relaxants such as **methocarbamol** (p 465). However, these therapies are often ineffective when used alone.
- c. Equine-derived antivenin (**antivenin *Latrodectus mactans***; see p 409) is rapidly effective, but rarely used because symptomatic therapy is often adequate and because of the small risk of anaphylaxis. It may still be indicated for seriously ill, elderly, or pediatric patients who do not respond to conventional therapy for hypertension, muscle cramping, or respiratory distress and for pregnant victims threatening premature labor.

2. *Loxosceles*. Therapy for necrotic arachnidism has been difficult to evaluate because of the inherent difficulty of accurate diagnosis.

- a. Dapsone has shown some promise in reducing the severity of necrotic ulcers in anecdotal case reports, but has not been effective in controlled animal models.
- b. Steroids are not usually recommended.
- c. A goat-derived antivenin has been studied, but is not FDA approved or commercially available.
- d. Hyperbaric oxygen has been proposed for significant necrotic ulcers, but results from animal studies are equivocal, and insufficient data exist to recommend its use.

C. Decontamination. These measures are not applicable. There is no proven value in the sometimes popular early excision of *Loxosceles* bites to prevent necrotic ulcer formation.**D. Enhanced elimination.** These procedures are not applicable.

Vetter RS: Myth: idiopathic wounds are often due to brown recluse or other spider bites throughout the United States. *West J Med* 2000;173(5):357–358. [PMID: 11069881] (The author, an entomologist at UC Riverside, offers to identify any suspected brown recluse spider. For more information, go to <http://spiders.ucr.edu/challenge.html>.)

Wright SW et al: Clinical presentation and outcome of brown recluse spider bite. *Ann Emerg Med* 1997;30(1):28–32. [PMID: 9209221] (Retrospective analysis of 111 patients; only 5% were ill enough to be admitted, and there were no deaths or serious complications.)

► STRYCHNINE

Saralyn R. Williams, MD

Strychnine is an alkaloid derived from the seeds of a tree, *Strychnos nux-vomica*. At one time strychnine was an ingredient in a variety of over-the-counter tonics and laxatives. Today strychnine is no longer used in any pharmaceuticals. Instead it is used primarily as a rodenticide and is sometimes found as an adulterant in illicit drugs such as cocaine or heroin.

I. Mechanism of toxicity

A. Strychnine competitively antagonizes glycine, an inhibitory neurotransmitter released by postsynaptic inhibitory neurons in the spinal cord. This causes increased neuronal excitability, which results in generalized seizure-like contraction of skeletal muscles. Simultaneous contraction of opposing flexor and extensor muscles causes severe muscle injury, with rhabdomyolysis, myoglobinuria, and, in some cases, acute renal failure.

B. Pharmacokinetics. Strychnine is rapidly absorbed after ingestion. The volume of distribution is very large ($V_d = 13 \text{ L/kg}$). Elimination is by hepatic metabolism with a half-life of about 10 hours after overdose.

II. Toxic dose. It is difficult to establish a toxic dose, although 16 mg was fatal in an adult in one case. Because life-threatening clinical manifestations can occur rapidly and because management decisions are based on clinical findings rather than on a history of ingested amounts, any dose of strychnine should be considered life threatening.

III. Clinical presentation. Symptoms and signs usually develop within 15–30 minutes of ingestion and may last several hours (the serum elimination half-life of strychnine was 10 hours in one reported overdose).

A. Muscular stiffness and painful cramps precede generalized muscle contractions and opisthotonus. The face may be drawn into a forced grimace (“sardonic grin,” or *risus sardonicus*). Muscle contractions are intermittent and are easily triggered by emotional or physical stimuli. Repeated and prolonged muscle contractions often result in hyperthermia, rhabdomyolysis, myoglobinuria, and renal failure.

B. Muscle spasms may resemble the tonic phase of a grand mal seizure, but strychnine does not cause true convulsions, and the patient is awake and painfully aware of the contractions.

C. Victims may also experience hyperacusis, hyperalgesia, and increased visual stimulation. Sudden noises or other sensory input may trigger muscle contractions.

D. Death is usually caused by respiratory arrest owing to intense contraction of the respiratory muscles. Death may also be secondary to hyperthermia or rhabdomyolysis and renal failure.

IV. Diagnosis is based on a history of ingestion of a rodenticide or recent intravenous drug abuse and the presence of seizure-like generalized muscle contractions, often accompanied by hyperthermia, lactic acidosis, and rhabdomyolysis (with myoglobinuria and elevated serum creatine phosphokinase [CPK]). In the differential diagnosis (see Table I-16, p 27), one should consider other causes of generalized muscle rigidity such as a black widow spider bite (p 346), neuroleptic malignant syndrome (p 22), or tetanus (see p 351).

A. Specific levels. Strychnine can be measured in the gastric fluid, urine, or blood. The toxic serum concentration is reported to be 1 mg/L, although in general, blood levels do not correlate well with the severity of toxicity.

B. Other useful laboratory studies include electrolytes, BUN, creatinine, CPK, arterial blood gases or oximetry, and urine test for occult blood (positive in the presence of urine myoglobinuria).

V. Treatment**A. Emergency and supportive measures**

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat hyperthermia (see p 21), metabolic acidosis (p 33), and rhabdomyolysis (p 27) if they occur.
3. Limit external stimuli such as noise, light, and touch.
4. **Treat muscle spasms aggressively.**

a. Administer **diazepam** (see p 415), 0.1–0.2 mg/kg IV, or **midazolam**, 0.05–0.1 mg/kg IV, to patients with mild muscle contractions. Give **morphine** (p 468) for pain relief. **Note:** These agents may impair respiratory drive.

- b. In more severe cases, use **pancuronium**, 0.06–0.1 mg/kg IV, or another nondepolarizing neuromuscular blocker (see p 472) to produce complete neuromuscular paralysis. **Caution:** Neuromuscular paralysis will cause respiratory arrest; patients will need endotracheal intubation and assisted ventilation.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal, if available. Do **not** induce vomiting because of the risk of aggravating muscle spasms.
2. **Hospital.** Administer activated charcoal orally or by gastric tube. Gastric lavage is not necessary for small ingestions if activated charcoal can be given promptly.

D. Enhanced elimination. Symptoms usually abate within several hours and can be managed effectively with intensive supportive care, so there is little to be gained from accelerated drug removal by dialysis or hemoperfusion. The use of repeat-dose activated charcoal has not been studied.

► SULFUR DIOXIDE

John Balmes, MD

Sulfur dioxide is a colorless, nonflammable gas formed by the burning of materials that contain sulfur. It is a major air pollutant from automobiles, smelters, and plants burning soft coal or oils high in sulfur content. It is soluble in water to form sulfurous acid, which may be oxidized to sulfuric acid; both are components of acid rain. Occupational exposures to sulfur dioxide occur in ore and metal refining, chemical manufacturing, and wood pulp treatment and in its use as a disinfectant, refrigerant, and dried-food preservative.

- I. **Mechanism of toxicity.** Sulfur dioxide is an irritant because it rapidly forms sulfurous acid on contact with moist mucous membranes. Most effects occur in the upper respiratory tract because 90% of inhaled sulfur dioxide is rapidly deposited there, but with very large exposures sufficient gas reaches the lower airways to cause chemical pneumonitis and pulmonary edema.
- II. **Toxic dose.** The sharp odor or taste of sulfur dioxide is noticed at 1–5 ppm. Throat and conjunctival irritation begins at 8–12 ppm and is severe at 50 ppm. The ACGIH-recommended workplace permissible limit (TLV-TWA) is 2 ppm (5.2 mg/m³) as an 8-hour time-weighted average, the short-term exposure limit (STEL) is 5 ppm (13 mg/m³), and the air level considered immediately dangerous to life or health (IDLH) is 100 ppm. Persons with asthma may experience bronchospasm with brief exposure to 0.5–1 ppm.
- III. **Clinical presentation**
 - A. **Acute exposure** causes burning of the eyes, nose, and throat; lacrimation; and cough. Laryngospasm may occur. Wheezing may be seen in normal subjects as well as asthmatics. Chemical bronchitis is not uncommon. With a very high-level exposure, chemical pneumonitis and noncardiogenic pulmonary edema may occur.
 - B. **Asthma and chronic bronchitis** may be exacerbated.
 - C. **Sulfhemoglobinemia** due to absorption of sulfur has been reported.
 - D. **Frostbite** injury to the skin may occur from exposure to liquid sulfur dioxide.

- IV. Diagnosis** is based on a history of exposure and the presence of airway and mucous membrane irritation. Symptoms usually occur rapidly after exposure.
- A. Specific levels.** Blood levels are not available.
 - B. Other useful laboratory studies** include arterial blood gases or oximetry, chest x-ray, and spirometry or peak expiratory flow rate.
- V. Treatment**
- A. Emergency and supportive measures**
 1. Remain alert for progressive upper-airway edema or obstruction, and be prepared to intubate the trachea and assist ventilation if necessary (see pp 1–7).
 2. Administer humidified oxygen, treat wheezing with bronchodilators (see p 8), and observe the victim for at least 4–6 hours for development of pulmonary edema (p 7).
 - B. Specific drugs and antidotes.** There is no specific antidote.
 - C. Decontamination**
 1. **Inhalation.** Remove the victim from exposure and give supplemental oxygen if available.
 2. **Skin and eyes.** Wash exposed skin and eyes with copious tepid water or saline. Treat frostbite injury as for thermal burns.
 - D. Enhanced elimination.** There is no role for these procedures.

Pandya RJ et al: Diesel exhaust and asthma: hypotheses and molecular mechanisms of action. *Environ Health Perspect* 2002;110(suppl 1):103–112. [PMID: 11834468] (Review.)

► TETANUS

Karl A. Sporer, MD

Tetanus is a rare disease in the United States, with fewer than 50 cases reported annually. It is caused by an exotoxin produced by *Clostridium tetani*, an anaerobic, spore-forming, gram-positive rod found widely in soil and in the gastrointestinal tract. Tetanus is typically seen in older persons (especially older women), recent immigrants, and intravenous drug users who have not maintained adequate tetanus immunization.

- I. Mechanism of toxicity.** The growth of *C tetani* in a wound under anaerobic conditions produces the toxin tetanospasmin. The toxin enters the myoneural junction of alpha motor neurons and travels via retrograde axonal transport to the synapse. There it blocks the release of the presynaptic inhibitory neurotransmitters gamma-aminobutyric acid (GABA) and glycine, causing intense muscular spasms.
- II. Toxic dose.** Tetanospasmin is an extremely potent toxin. Fatal tetanus can result from a minor puncture wound in a susceptible individual.
- III. Clinical presentation.** The incubation period between the initial wound and development of symptoms averages 1–2 weeks (range 2–56 days). The wound is not apparent in about 5% of cases. Wound cultures are positive for *C tetani* only about one-third of the time.
 - A.** The most common initial complaint is pain and stiffness of the jaw, progressing to trismus, *risus sardonicus*, and opisthotonus over several days. Uncontrollable and painful reflex spasms involving all muscle groups are precipitated by minimal stimuli and can result in fractures, rhabdomyolysis, hyperpyrexia, and asphyxia. The patient remains awake during the spasms. In survivors, the spasms may persist for days or weeks.
 - B.** A syndrome of sympathetic hyperactivity often accompanies the muscular manifestations, with hypertension, tachycardia, arrhythmias, and diaphoresis.
 - C.** Neonatal tetanus occurs frequently in developing countries, owing to inadequate maternal immunity and poor hygiene, especially around the necrotic umbilical stump. Localized tetanus has been reported, involving rigidity and

spasm only in the affected limb. Cephalic tetanus is uncommonly associated with head wounds and involves primarily the cranial nerves.

IV. Diagnosis is based on the finding of characteristic muscle spasms in an awake person with a wound and an inadequate immunization history. Strychnine poisoning (see p 348) produces identical muscle spasms and should be considered in the differential diagnosis. Other considerations include hypocalcemia and dystonic reactions.

A. Specific levels. There are no specific toxin assays. A serum antibody level of 0.01 IU/mL or greater suggests prior immunity and makes the diagnosis less likely.

B. Other useful laboratory studies include electrolytes, glucose, calcium, BUN, creatinine, CPK, arterial blood gases, and urine dipstick for occult blood (positive with myoglobinuria). A diagnostic electromyographic pattern has been described but is not commonly used.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat hyperthermia (see p 21), arrhythmias (pp 10–15), metabolic acidosis (p 33), and rhabdomyolysis (p 27) if they occur.
3. Limit external stimuli such as noise, light, and touch.

4. Treat muscle spasms aggressively:

- a. Administer **diazepam** (see p 415), 0.1–0.2 mg/kg IV, or **midazolam**, 0.05–0.1 mg/kg IV, to patients with mild muscle contractions. Give **morphine** (see p 468) for pain relief. **Note:** These agents may impair respiratory drive.
- b. In more severe cases, use **pancuronium**, 0.06–0.1 mg/kg IV, or another neuromuscular blocker (see p 472), to produce complete neuromuscular paralysis. **Caution:** Neuromuscular paralysis will cause respiratory arrest; patients will need endotracheal intubation and assisted ventilation.

B. Specific drugs and antidotes

1. **Human tetanus immune globulin (TIG)**, 3000–5000 IU administered IM, will neutralize circulating toxin but has no effect on toxin already fixed to neurons. TIG should be given as early as possible to a patient with suspected tetanus and to persons with a fresh wound but possibly inadequate prior immunization.
2. **Prevention** can be ensured by an adequate immunization series with tetanus toxoid in childhood and repeated boosters at 10-year intervals. Survival of tetanus may not protect against future exposures, because the small amount of toxin required to cause disease is inadequate to confer immunity.

C. Decontamination. Thoroughly debride and irrigate the wound, and administer appropriate antibiotics (penicillin is adequate for *C tetani*).

D. Enhanced elimination. There is no role for these procedures.

Cook TM et al: Tetanus: a review of the literature. *Br J Anaesth* 2001;87(3):477–487. [PMID: 11517134] (A thorough review of hospital treatment with excellent references.)

Hsu SS, Groleau G: Tetanus in the emergency department: a current review. *J Emerg Med* 2001;20(4):357–365. [PMID: 11348815] (Excellent review of the clinical features of tetanus.)

► THALLIUM

Thomas J. Ferguson, MD, PhD

Thallium is a soft metal that quickly oxidizes upon exposure to air. It is a minor constituent in a variety of ores. Thallium salts are used in the manufacture of jewelry, semiconductors, and optical devices. Thallium is no longer used in the United States as a depilatory or a rodenticide because of its high human toxicity.

- I. Mechanism of toxicity.** The mechanism of thallium toxicity is not known. It appears to affect a variety of enzyme systems, resulting in generalized cellular poisoning. Thallium metabolism has some similarities to that of potassium, and it may inhibit potassium flux across biological membranes by binding to Na-K ATP transport enzymes.
- II. Toxic dose.** The minimum lethal dose of thallium salts is probably 12–15 mg/kg, although toxicity varies widely depending on the compound, and there are reports of death after adult ingestion of as little as 200 mg. The more water-soluble salts (eg, thallos acetate and thallic chloride) are slightly more toxic than the less soluble forms (thallic oxide and thallos iodide). Some thallium salts are well absorbed across intact skin.
- III. Clinical presentation.** Symptoms do not occur immediately but are typically delayed 12–14 hours after ingestion.
- A. Acute effects** include abdominal pain, nausea, vomiting, and diarrhea (sometimes with hemorrhage). Shock may result from massive fluid or blood loss. Within 2–3 days, delirium, seizures, respiratory failure, and death may occur.
- B. Chronic effects** include painful peripheral neuropathy, myopathy, chorea, stomatitis, and ophthalmoplegia. Hair loss and nail dystrophy (Mees' lines) may appear after 2–4 weeks.
- IV. Diagnosis.** Thallotoxicosis should be considered when gastroenteritis and painful paresthesia are followed by alopecia.
- A. Specific levels.** Urinary thallium is normally less than 0.8 mcg/L. Concentrations greater than 20 mcg/L are evidence of excessive exposure and may be associated with subclinical toxicity during workplace exposures. Blood thallium levels are not considered reliable measures of exposure, except after large exposures. Hair levels are of limited value, mainly in documenting past exposure or in forensic cases.
- B. Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, creatinine, and hepatic transaminases. Since thallium is radiopaque, plain abdominal x-rays may be useful after acute ingestion.
- V. Treatment**
- A. Emergency and supportive measures**
1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Treat seizures (see p 22) and coma (p 19) if they occur.
 3. Treat gastroenteritis with aggressive intravenous replacement of fluids (and blood if needed). Use pressors only if shock does not respond to fluid therapy (see p 16).
- B. Specific drugs and antidotes.** There is currently no recommended specific treatment in the United States.
1. **Prussian blue** (ferric ferrocyanide) is the mainstay of therapy in Europe. This compound has a crystal lattice structure, which binds thallium ions and interrupts enterohepatic recycling. The recommended dose is 250 mg/kg/day via nasogastric tube in 2–4 divided doses, and administration is continued until urinary thallium excretion is less than 0.5 mg/24 h. Prussian blue appears to be nontoxic at these doses. In the United States, Prussian blue is available as an investigational new drug (IND) through the Oak Ridge Associated Universities ([865] 576-3131 or [865] 576-3300).
 2. **Activated charcoal** is readily available and has been shown to bind thallium in vitro. Multiple-dose charcoal is recommended because thallium apparently undergoes enterohepatic recirculation. In one study, charcoal was shown to be superior to Prussian blue in eliminating thallium.
 3. **BAL** (see p 413) and other chelators have been tried with varying success. Penicillamine and diethyldithiocarbamate should be avoided because of studies suggesting they contribute to redistribution of thallium to the brain.
- C. Decontamination** (see p 46)
1. **Prehospital.** Administer activated charcoal if available. Ipecac-induced vomiting may be useful for initial treatment at the scene (eg, children at home) if it can be given within a few minutes of exposure.

2. **Hospital.** Administer activated charcoal. Consider gastric lavage for large recent ingestion.
- D. **Enhanced elimination.** Repeat-dose activated charcoal may enhance fecal elimination by binding thallium secreted into the gut lumen or via the biliary system, interrupting enterohepatic or enteroenteric recirculation. Forced diuresis, dialysis, and hemoperfusion are of no proven benefit.

Hoffman RS et al: Comparative efficacy of thallium adsorption by activated charcoal, Prussian blue, and sodium polystyrene sulfonate. *J Toxicol Clin Toxicol* 1999;37(7):833–837. [PMID: 10630266] (In vitro study supports utility of both activated charcoal and Prussian blue as thallium adsorbents.)

Rusyniak DE et al: Thallium and arsenic poisoning in a small midwestern town. *Ann Emerg Med* 2002;39(3):307–311. [PMID: 11867986] (Thallium and arsenic toxicity following criminal poisoning of a group of men.)

► THEOPHYLLINE

Kent R. Olson, MD

Theophylline is a methylxanthine used for the treatment of asthma. Intravenous infusions of aminophylline, the ethylenediamine salt of theophylline, are used to treat bronchospasm, congestive heart failure, and neonatal apnea. Theophylline is most commonly used orally in sustained-release preparations (eg, Theo-Dur™, Slo-Phyllin™, Theo-24™, and many others).

I. Mechanism of toxicity

- A. The exact mechanism of toxicity is not known. Theophylline is an antagonist of adenosine receptors, and it inhibits phosphodiesterase at high levels, increasing intracellular cyclic adenosine monophosphate (cAMP). It also is known to release endogenous catecholamines at therapeutic concentrations and may itself stimulate beta-adrenergic receptors.

- B. **Pharmacokinetics.** Absorption may be delayed with sustained-release preparations. The volume of distribution (Vd) is approximately 0.5 L/kg. The normal elimination half-life is 4–6 hours; this may be doubled by illnesses or interacting drugs that slow hepatic metabolism, such as liver disease, congestive heart failure, influenza, erythromycin, or cimetidine, and may increase to as much as 20 hours after overdose. (See also Table II–59, p 381.)

- II. **Toxic dose.** An acute single dose of 8–10 mg/kg could raise the serum level by up to 15–20 mg/L, depending on the rate of absorption. Acute oral overdose of more than 50 mg/kg may potentially result in a level above 100 mg/L and severe toxicity.

- III. **Clinical presentation.** Two distinct syndromes of intoxication may occur, depending on whether the exposure is **acute** or **chronic**.

- A. **Acute single overdose** is usually a result of a suicide attempt or accidental childhood ingestion but may also be caused by accidental or iatrogenic misuse (therapeutic overdose).

1. Usual manifestations include vomiting (sometimes with hematemesis), tremor, anxiety, and tachycardia. Metabolic effects include pronounced hypokalemia, hypophosphatemia, hyperglycemia, and metabolic acidosis.
2. With serum levels above 90–100 mg/L, hypotension, ventricular arrhythmias, and seizures are common; status epilepticus is frequently resistant to anticonvulsant drugs.
3. Seizures and other manifestations of severe toxicity may be delayed 12–16 hours or more after ingestion, in part owing to delayed absorption of drug from sustained-release preparations.

- B. **Chronic intoxication** occurs when excessive doses are administered repeatedly over 24 hours or longer or when intercurrent illness or an interacting drug interferes with hepatic metabolism of theophylline. The usual victims are very

young infants or elderly patients, especially those with chronic obstructive lung disease.

1. Vomiting may occur but is not as common as in acute overdose. Tachycardia is common, but hypotension is rare. Metabolic effects such as hypokalemia and hyperglycemia do not occur.
2. Seizures may occur with lower serum levels (eg, 40–60 mg/L) and have been reported with levels as low as 20 mg/L.

IV. Diagnosis is based on a history of ingestion or the presence of tremor, tachycardia, and other manifestations in a patient known to be on theophylline. Hypokalemia strongly suggests acute overdose rather than chronic intoxication.

A. Specific levels. Serum theophylline levels are essential for diagnosis and determination of emergency treatment. After acute oral overdose, obtain repeated levels every 2–4 hours; single determinations are not sufficient, because continued absorption from sustained-release preparations may result in peak levels 12–16 hours or longer after ingestion.

1. Levels less than 90–100 mg/L after acute overdose are not usually associated with severe symptoms such as seizures or ventricular arrhythmias.
2. However, with chronic intoxication, severe toxicity may occur with levels of 40–60 mg/L. **Note:** Acute caffeine overdose (see p 142) will cause a similar clinical picture and will produce falsely elevated theophylline concentrations with most commercial immunoassays.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, hepatic function tests, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat seizures (see p 22), arrhythmias (pp 12–15), and hypotension (p 16) if they occur. Tachyarrhythmias and hypotension are best treated with a beta-adrenergic agent (see B, below).
3. Hypokalemia is caused by intracellular movement of potassium and does not reflect a significant total body deficit; it usually resolves spontaneously without aggressive treatment.
4. Monitor vital signs, ECG, and serial theophylline levels for at least 16–18 hours after a significant oral overdose.

B. Specific drugs and antidotes. Hypotension, tachycardia, and ventricular arrhythmias are caused primarily by excessive beta-adrenergic stimulation. Treat with low-dose **propranolol** (see p 496), 0.01–0.03 mg/kg IV, or **esmolol** (see p 443), 0.025–0.05 mg/kg/min. Use beta blockers cautiously in patients with a prior history of asthma or wheezing.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary for small ingestions if activated charcoal can be given promptly.
3. Undissolved sustained-release tablets may not be removed with even the largest (40F) gastric tube. For significant ingestions, consider the following special techniques:
 - a. Administer repeated doses of activated charcoal (see p 57).
 - b. Perform whole-bowel irrigation (see p 52).

D. Enhanced elimination (see p 54). Theophylline has a small volume of distribution (0.5 L/kg) and is efficiently removed by hemodialysis, charcoal hemoperfusion, or repeat-dose activated charcoal.

1. **Hemodialysis or hemoperfusion** should be performed if the patient is in status epilepticus or if the serum theophylline concentration is greater than 100 mg/L.

2. **Repeat-dose activated charcoal** (see p 57) is not as effective but may be used for stable patients with levels below 100 mg/L.

Polak M et al: Theophylline intoxication mimicking diabetic ketoacidosis in a child. *Diabetes Metab* 1999;25(6):513–515. [PMID: 10633877] (A 5-year-old boy with vomiting, hyperglycemia, ketonuria, and acidosis.)

► **THYROID HORMONE**

F. Lee Cantrell, PharmD

Thyroid hormone is available as synthetic triiodothyronine (T₃, or liothyronine), synthetic tetraiodothyronine (T₄, levothyroxine), or natural desiccated animal thyroid (containing both T₃ and T₄; Table II–55). Despite concern over the potentially life-threatening manifestations of thyrotoxicosis, serious toxicity rarely occurs after acute thyroid hormone ingestion.

- I. **Mechanism of toxicity.** Excessive thyroid hormone potentiates adrenergic activity in the cardiovascular, gastrointestinal, and neurologic systems. The effects of T₃ overdose are manifested within the first 6 hours after ingestion. In contrast, symptoms of T₄ overdose may be delayed 2–5 days after ingestion while metabolic conversion to T₃ occurs.
- II. **Toxic dose**
- A. An acute ingestion of more than 5 mg of **levothyroxine** (T₄) or 0.75 mg of **triiodothyronine** (T₃) is considered potentially toxic. An adult has survived an ingestion of 48 g of unspecified thyroid tablets; a 15-month-old child had moderate symptoms after ingesting 1.5 g of desiccated thyroid.
- B. Euthyroid persons and children appear to have a high tolerance to the effects of an acute overdose. Patients with preexisting cardiac disease and those with chronic overmedication have a lower threshold of toxicity. Sudden deaths have been reported after chronic thyroid hormone abuse in healthy adults.
- III. **Clinical presentation.** The effects of an acute T₄ overdose may not be evident for several days because of a delay for metabolism of T₄ to more active T₃.
- A. **Mild to moderate intoxication** may cause sinus tachycardia, elevated temperature, flushing, diarrhea, vomiting, headache, anxiety, agitation, psychosis, and confusion.
- B. **Severe toxicity** may include supraventricular tachycardia, hyperthermia, and hypotension. There is one case report of a seizure after acute overdose.
- IV. **Diagnosis** is based on a history of ingestion and signs and symptoms of increased sympathetic activity.
- A. **Specific levels**
1. **Levothyroxine (T₄).** Serious poisoning is very unlikely, and blood levels may not be required unless symptoms develop over 5–7 days after the ingestion. In this case, obtain free T₃ and T₄ concentrations, or total T₃ and T₄ levels with T₃ resin uptake.
2. **Thyroid USP or triiodothyronine (T₃).** Serious poisoning is more likely. Obtain free and total T₃ levels approximately 2–6 hours after an acute ingestion; repeat over the following 5–7 days. There is a reasonable qualita-

TABLE II–55. DOSAGE EQUIVALENTS OF THYROID HORMONE

Thyroid USP	65 mg (1 grain)
Thyroxine (T ₄ , levothyroxine)	0.1 mg (100 mcg)
Triiodothyronine (T ₃)	0.025 mg (25 mcg)

tive relationship between the presence of elevated levels and the presence of symptoms.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
2. Treat seizures (see p 22), hyperthermia (p 21), hypotension (p 16), and arrhythmias (pp 12–15) if they occur.
3. Repeated evaluation over several days is recommended after large T_4 or combined ingestions, because serious symptoms may be delayed.
4. Most patients will suffer no serious toxicity or will recover with simple supportive care.

B. Specific drugs and antidotes

1. Treat serious tachyarrhythmias with **propranolol** (see p 496), 0.01–0.1 mg/kg IV repeated every 2–5 minutes to desired effect, or **esmolol** (see p 443), 0.025–0.1 mg/kg/min IV. Simple sinus tachycardia may be treated with oral propranolol, 0.1–0.5 mg/kg every 4–6 hours.
2. Peripheral metabolic conversion of T_4 to T_3 can be partially inhibited by **propylthiouracil**, 6–10 mg/kg/day (maximum 1 g) divided into three oral doses, for 5–7 days.
3. **Iopanoic acid**. Doses of 125 mg orally for up to 6 days were used adjunctively in an acute massive pediatric T_4 ingestion refractory to propranolol and PTU therapy.

C. Decontamination (see p 47)

1. **Prehospital**. Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
2. **Hospital**. Administer activated charcoal. Gastric emptying is not necessary after small ingestions if activated charcoal can be given promptly.

D. Enhanced elimination. Diuresis and hemodialysis are not useful because thyroid hormones are extensively protein bound. Charcoal hemoperfusion may be effective, but limited data are available. Exchange transfusion has been performed in children and adults, but data on its efficacy are limited.

Brown RS et al: Successful treatment of massive acute thyroid hormone poisoning with iopanoic acid. *J Pediatr* 1998;132(5):903–905. [PMID: 9602214] (Within 12 hours after a single dose of iopanoic acid there was a marked clinical and hormonal response.)

Tunget CL0 et al: Raising the decontamination level for thyroid hormone ingestions. *Am J Emerg Med* 1995;13(1):9–13. [PMID: 7832964] (Significant toxicity is unlikely with doses less than 5 mg T_4 .)

► TOLUENE AND XYLENE

Janet Weiss, MD

Toluene (methylbenzene) and xylene (dimethylbenzene and xylol) are very common aromatic solvents widely used in glues, inks, dyes, lacquers, varnishes, paints, paint removers, pesticides, cleaners, and degreasers. The largest source of exposure to toluene is in the production and use of gasoline. Toluene is also frequently abused intentionally by inhaling paints containing toluene to induce a “sniffer’s high.”

I. Mechanism of toxicity

A. Toluene and xylene cause generalized central nervous system depression. Like other aromatic hydrocarbons, they may sensitize the myocardium to the arrhythmogenic effects of catecholamines. They are mild mucous membrane irritants affecting the eyes and respiratory and gastrointestinal tracts.

- B. Pulmonary aspiration can cause a hydrocarbon pneumonitis (see p 219).
- C. Chronic abuse of toluene can cause diffuse CNS demyelination, renal tubular damage, and myopathy.
- D. **Kinetics.** Toluene is metabolized by alcohol dehydrogenase, and the presence of ethanol can inhibit toluene metabolism and prolong systemic toxicity.

II. Toxic dose

- A. **Ingestion.** As little as 15–20 mL of toluene is reported to cause serious toxicity. A 60-mL dose was fatal in an adult male, with death occurring within 30 minutes.
- B. **Inhalation.** The recommended workplace limits (ACGIH TLV-TWA) are 50 ppm (188 mg/m³) for toluene and 100 ppm (434 mg/m³) for xylene, as 8-hour time-weighted averages, with a “skin” notation indicating the potential for appreciable skin absorption. The air levels considered immediately dangerous to life or health (IDLH) are 500 ppm for toluene and 900 ppm for xylene.
- C. Prolonged **dermal** exposure may cause chemical burns; both toluene and xylene are well absorbed across the skin.

III. Clinical presentation.

Toxicity may be a result of ingestion, pulmonary aspiration, or inhalation.

- A. **Ingestion** of toluene or xylene may cause vomiting and diarrhea, and if pulmonary aspiration occurs, chemical pneumonitis may result. Systemic absorption may lead to CNS depression.
- B. **Inhalation** produces euphoria, dizziness, headache, nausea, and weakness. Exposure to high concentrations may rapidly cause delirium, coma, pulmonary edema, respiratory arrest, and death. Arrhythmias may occasionally occur due to cardiac sensitization. Both tachydysrhythmias and bradydysrhythmias have been reported.
- C. **Chronic exposure** to toluene may cause permanent CNS impairment, including tremors; ataxia; brainstem, cerebellar, and cerebral atrophy; and cognitive and neurobehavioral abnormalities. Myopathy, hypokalemia, and renal tubular acidosis are also common. Animal studies suggest that toluene may cause adverse reproductive effects.

IV. Diagnosis

is based on a history of exposure and typical manifestations of acute CNS effects such as euphoria or “drunkenness.” After acute ingestion, pulmonary aspiration is suggested by coughing, choking, tachypnea, or wheezing and is confirmed by chest x-ray.

- A. **Specific levels.** In acute symptomatic exposures, toluene or xylene may be detectable in blood drawn with a gas-tight syringe, but usually only for a few hours. The metabolites hippuric acid, ortho-cresol (toluene), and methylhippuric acid (xylene) are excreted in the urine and can be used to document exposure, but urine levels do not correlate with systemic effects.
- B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, liver transaminases, CPK, and urinalysis.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen, and monitor arterial blood gases and chest x-rays.
 - a. If the patient is coughing or dyspneic, aspiration pneumonia is likely. Treat as for hydrocarbon pneumonia (see p 219).
 - b. If the patient remains asymptomatic after a 6-h observation period, chemical pneumonia is unlikely and further observation or chest x-ray is not needed.
2. Treat coma (see p 19), arrhythmias (pp 12–15), and bronchospasm (p 8) if they occur. **Caution:** Epinephrine and other sympathomimetic amines can provoke or aggravate cardiac arrhythmias. Tachyarrhythmias may be treated with **propranolol** (p 496), 1–2 mg IV, or **esmolol** (p 443), 0.025–0.1 mg/kg/min IV.

- B. **Specific drugs and antidotes.** There is no specific antidote.

C. Decontamination. Rescuers should treat heavily contaminated victims in a well-ventilated area or should use self-contained breathing apparatus or other appropriate respiratory protection, as well as chemical-resistant clothing and gloves.

1. Inhalation. Remove the victim from exposure and give supplemental oxygen if available.

2. Skin and eyes. Remove contaminated clothes and wash exposed skin with soap and water. Irrigate exposed eyes with copious tepid water or saline.

3. Ingestion (see p 47)

a. Prehospital. Administer activated charcoal if available. Do **not** induce vomiting because of the risk of rapidly progressive CNS depression.

b. Hospital. Administer activated charcoal. Consider gastric lavage for large ingestions (> 1–2 oz) if it can be performed within 30 minutes of ingestion.

D. Enhanced elimination. There is no role for enhanced elimination.

► TRICHLOROETHANE, TRICHLOROETHYLENE, AND PERCHLOROETHYLENE

Diane Liu, MD, MPH

Trichloroethane and trichloroethylene are widely used solvents found as ingredients in many products, including typewriter correction fluid (“white-out”), color film cleaners, insecticides, spot removers, fabric cleaning solutions, adhesives, and paint removers. They are used extensively in industry as degreasers. Trichloroethane is available in two isomeric forms, 1,1,2- and 1,1,1-, with the latter (also known as methyl chloroform) being the most common. Perchloroethylene (tetrachloroethylene) is another related solvent used widely in the dry cleaning industry.

I. Mechanism of toxicity

A. These solvents act as respiratory and central nervous system depressants and skin and mucous membrane irritants. They have rapid anesthetic action, and both trichloroethylene and trichloroethane were used for this purpose medically until the advent of safer agents.

B. Trichloroethane, trichloroethylene, their metabolite trichloroethanol, and perchloroethylene may sensitize the myocardium to the arrhythmogenic effects of catecholamines.

C. Trichloroethylene or a metabolite may act to inhibit acetaldehyde dehydrogenase, blocking the metabolism of ethanol and causing “degreaser’s flush.”

D. Carcinogenicity. The National Institute of Occupational Safety and Health (NIOSH) and the International Agency for Research on Cancer (IARC) consider perchloroethylene and trichloroethylene probable carcinogens. While 1,1,2-trichloroethane is a NIOSH-suspected carcinogen, there is insufficient evidence to label 1,1,1-trichloroethane a carcinogen.

II. Toxic dose

A. Trichloroethane. The acute lethal oral dose to humans is reportedly between 0.5–5 mL/kg. The recommended workplace limits (ACGIH TLV-TWA) in air for the 1,1,1- and 1,1,2- isomers are 350 and 10 ppm, respectively, and the air levels considered immediately dangerous to life or health (IDLH) are 700 and

100 ppm, respectively. Anesthetic levels are in the range of 10,000–26,000 ppm. The odor is detectable by a majority of people at 500 ppm, but olfactory fatigue commonly occurs.

B. Trichloroethylene. The acute lethal oral dose is reported to be approximately 3–5 mL/kg. The recommended workplace limit (ACGIH TLV-TWA) is 50 ppm (269 mg/m³), and the air level considered immediately dangerous to life or health (IDLH) is 1000 ppm.

C. Perchloroethylene. The recommended workplace limit (ACGIH TLV-TWA) is 25 ppm (170 mg/m³), and the air level considered immediately dangerous to life or health (IDLH) is 150 ppm.

III. Clinical presentation. Toxicity may be a result of inhalation, skin contact, or ingestion.

A. Inhalation or ingestion may cause nausea, euphoria, ataxia, dizziness, agitation, and lethargy, and if intoxication is significant, respiratory arrest, seizures, and coma. Hypotension and cardiac arrhythmias may occur. With severe overdose, renal and hepatic injury may be apparent 1–2 days after exposure.

B. Local effects of exposure to liquid or vapors include irritation of the eyes, nose, and throat. Prolonged skin contact can cause defatting and dermatitis.

C. Ingestion. Aspiration into the tracheobronchial tree may result in hydrocarbon pneumonia (see p 219).

D. Degreaser's flush. Workers exposed to these vapors may have acute flushing and orthostatic hypotension if they ingest alcohol, owing to a disulfiram-like effect (see Disulfiram, p 186).

IV. Diagnosis is based on a history of exposure and typical symptoms. Addictive inhalational abuse of typewriter correction fluid suggests trichloroethylene poisoning.

A. Specific levels

1. Although trichloroethane can be measured in expired air, blood, and urine, levels are not routinely rapidly available and are not needed for evaluation or treatment. Confirmation of exposure might be possible by detecting the metabolite trichloroethanol in the blood or urine. Hospital laboratory methods are not usually sensitive to these amounts.

2. Breath analysis is becoming more widely used for workplace exposure control, and serial measurements may allow for estimation of the amount absorbed.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, liver transaminases, arterial blood gases, and ECG monitoring.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen, and treat hydrocarbon aspiration pneumonia (p 219) if it occurs.

2. Treat seizures (see p 22), coma (p 19), and arrhythmias (pp 12–15) if they occur. **Caution:** Avoid the use of epinephrine or other sympathomimetic amines because of the risk of inducing or aggravating cardiac arrhythmias. Tachyarrhythmias caused by myocardial sensitization may be treated with **propranolol** (p 496), 1–2 mg IV, or **esmolol** (p 443), 0.025–0.1 mg/kg/min IV.

3. Monitor for a minimum of 4–6 hours after significant exposure.

B. Specific drugs and antidotes. There is no specific antidote.

C. Decontamination (see p 46)

1. **Inhalation.** Remove the victim from exposure and administer supplemental oxygen, if available.

2. **Skin and eyes.** Remove contaminated clothing and wash exposed skin with soap and water. Irrigate exposed eyes with copious tepid water or saline.

3. **Ingestion** (see p 49)

a. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting because of the danger of rapid absorption and abrupt onset of seizures or coma.

- b. Hospital.** Administer activated charcoal orally or by gastric tube. Consider gastric lavage; for small ingestions (< 30 mL), oral activated charcoal alone without gut emptying may be sufficient.

D. Enhanced elimination. These procedures are not effective or necessary.

► VACOR (PNU)

Neal L. Benowitz, MD

Vacor rat killer (2% *N*-3-pyridylmethyl-*N'*-*p*-nitrophenylurea; PNU) is a unique rodenticide that causes irreversible insulin-dependent diabetes and autonomic nervous system injury. It was removed from general sale in the United States in 1979 but is still available in some homes and for use by licensed exterminators. The product was sold in 39-g packets of cornmeal-like material containing 2% PNU.

- I. Mechanism of toxicity.** PNU is believed to antagonize the actions of nicotine and, in a manner similar to that of alloxan and streptozocin, injure pancreatic beta cells. The mechanisms of autonomic neuropathy and central nervous system effects are unknown. Adrenergic neurons acting on blood vessels but not the heart are affected. As a result, orthostatic hypotension associated with an intact reflex tachycardia is the usual picture.
- II. Toxic dose.** Acute toxicity has usually occurred after ingestion of one 39-g packet of Vacor (approximately 8 g of PNU). The smallest dose reported to cause toxicity was 390 mg.
- III. Clinical presentation.** Initial symptoms include nausea and vomiting. Occasionally, confusion, stupor, and coma occur after several hours. After a delay of several hours to days, irreversible autonomic neuropathy, peripheral neuropathy, and diabetes may occur.
 - A. Autonomic dysfunction.** Dizziness or syncope or both caused by severe orthostatic hypotension occur with an onset from 6 hours to 2 days after ingestion. Orthostatic hypotension is usually accompanied by intact reflex tachycardia. Other manifestations of autonomic neuropathy include dysphagia, recurrent vomiting, and constipation.
 - B. Insulin-dependent diabetes mellitus,** with polyuria, polydipsia, hyperglycemia, and ketoacidosis, occurs after a few days. Hypoglycemia, resulting from insulin release, occasionally precedes hyperglycemia.
 - C. Peripheral neuropathy** may cause paresthesias and muscle weakness.
- IV. Diagnosis.** Sudden onset of orthostatic hypotension or diabetes mellitus should suggest the possibility of Vacor ingestion. A careful investigation should be performed to determine what rat-killing chemicals may be present in the home.
 - A. Specific levels.** PNU levels are not available.
 - B. Other useful laboratory studies** include electrolytes, glucose, BUN, and creatinine.
- V. Treatment**
 - A. Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Orthostatic hypotension usually responds to supine positioning and intravenous fluids. Chronic therapy includes a high-salt diet and fludrocortisone (0.1–1 mg/day).
 3. Treat diabetes in the usual manner with fluids and insulin.

- B. Specific drugs and antidotes.** Immediately administer **nicotinamide** (see p 475). Although its efficacy in humans is not proved, nicotinamide can prevent PNU-induced diabetes in rats.
- C. Decontamination** (see p 47)
- 1. Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 - 2. Hospital.** Administer activated charcoal. For large ingestions (eg, more than one packet), consider gastric lavage and extra doses of charcoal (ie, to maintain 10:1 ratio of charcoal to PNU).
- D. Enhanced elimination.** Forced diuresis, dialysis, and hemoperfusion are not effective. Repeat-dose charcoal treatment has not been studied.

Seon YD et al: Changes of glomerular basement membrane components in Vacor-induced diabetic nephropathy. *Korean J Intern Med* 1999;14(1):77–84. [PMID: 10063318] (Rat study examining diabetic nephropathy following Vacor poisoning.)

► VALPROIC ACID

Thomas E. Kearney, PharmD

Valproic acid (Depakene or Depakote [divalproex sodium]) is a structurally unique anti-convulsant. It is used for the treatment of absence seizures, partial complex, and generalized seizure disorders and is a secondary agent for refractory status epilepticus. It is also commonly used for the prophylaxis and treatment of acute manic episodes and other affective disorders, migraine prophylaxis, and chronic pain syndromes.

I. Mechanism of toxicity

- A.** Valproic acid is a low-molecular-weight (144.21), branched-chain carboxylic acid ($pK_a = 4.8$) that increases levels of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and prolongs the recovery of inactivated sodium channels. These properties may be responsible for its action as a general central nervous system depressant. Valproic acid also alters amino acid and fatty acid metabolism with disruption of the urea cycle, and can cause hepatotoxicity, metabolic perturbations, cerebral edema, and bone marrow depression. Some of these effects may be associated with carnitine deficiency.

B. Pharmacokinetics

- Valproic acid is rapidly and completely absorbed from the gastrointestinal tract. There is a delay in the absorption with the preparation Depakote (divalproex sodium), because of its delayed-release formulation as well as the intestinal conversion of divalproex to 2 molecules of valproic acid.
- At therapeutic levels, valproic acid is highly protein bound (80–95%) and primarily confined to the extracellular space with a small (0.13–0.22 L/kg) volume of distribution (Vd). In overdose and at levels exceeding 90 mg/L, saturation of protein-binding sites occurs, resulting in a greater circulating free fraction of valproic acid and a larger Vd.
- Valproic acid is predominantly metabolized by the liver and may undergo some degree of enterohepatic recirculation. The elimination half-life is 5–20 hours (average 10.6 hours). In overdose, the half-life may be prolonged to as long as 30 hours. A level exceeding 1000 mg/L may not drop into the therapeutic range for at least 3 days. In addition, active metabolites (eg, the neurotoxic 2-en-valproic acid) may contribute to prolonged or delayed toxicity.

- II. Toxic dose.** The usual daily dose for adults is 1.2–1.5 g, to achieve therapeutic serum levels of 50–100 mg/L, and the suggested maximum daily dose is 60

mg/kg. Acute ingestions exceeding 200 mg/kg are associated with high risk for significant CNS depression. The lowest published fatal dose is 15 g (750 mg/kg) in a 20-month-old child, but adult patients have survived after ingestions of 75 g.

III. Clinical presentation

A. Acute overdose

1. Acute ingestion commonly causes gastrointestinal upset, variable CNS depression (confusion, disorientation, obtundation, and coma with respiratory failure), and occasionally hypotension with tachycardia and prolonged QT interval. The pupils may be miotic, and the presentation may mimic an opiate poisoning. Cardiorespiratory arrest has been associated with severe intoxication, and the morbidity and mortality from valproic acid poisoning seem to be related primarily to hypoxia and refractory hypotension.
2. Paradoxical seizures may occur in patients with a preexisting seizure disorder.
3. Transient rises of transaminase levels have been observed, without evidence of liver toxicity. Hyperammonemia with encephalopathy has been observed with therapeutic levels and in overdose, and without other evidence of hepatic dysfunction.
4. At very high serum levels (> 1000 mg/L) after large ingestions, other metabolic and electrolyte abnormalities may be observed, including an increased anion gap acidosis, hypocalcemia, and hypernatremia.
5. Other complications or late sequelae (days after ingestion) associated with severe intoxication may include optic nerve atrophy, cerebral edema, non-cardiogenic pulmonary edema, anuria, and pancreatitis.

B. Adverse effects of chronic valproic acid therapy include hepatic failure (high-risk patients are less than 2 years of age, receiving multiple anticonvulsants, or have other long-term neurologic complications) and weight gain. Hepatitis is not dose related and is not usually seen after an acute overdose. Pancreatitis is usually considered a non-dose-related effect. Alopecia, red cell aplasia, thrombocytopenia, and neutropenia have been associated with both acute and chronic valproic acid intoxication.

C. Valproic acid is a known human teratogen.

IV. Diagnosis is based on the history of exposure and typical findings of CNS depression and metabolic disturbances. The differential diagnosis is broad and includes most CNS depressants. Encephalopathy and hyperammonemia may mimic Reye's syndrome.

A. Specific levels. Obtain a stat serum valproic acid level. Serial valproic acid level determinations should be obtained, particularly after ingestion of divalproex-containing preparations (Depakote), owing to the potential for delayed absorption. Peak levels have been reported up to 18 hours after Depakote overdose, and could be even later after ingestion of the new formulation Depakote ER.

1. In general, serum levels exceeding 450 mg/L are associated with drowsiness or obtundation, and levels greater than 850 mg/L are associated with coma, respiratory depression, and metabolic perturbations. However, there appears to be poor correlation of serum levels with outcome. Moreover, assays may or may not include metabolites.
2. Death from acute valproic acid poisoning has been associated with peak levels ranging from 106–2728 mg/L, but survival was reported in a patient with a peak level of 2120 mg/L.

B. Other useful laboratory studies include electrolytes, glucose, BUN, creatinine, calcium, ammonia, liver transaminases, bilirubin, prothrombin time (PT), amylase, serum osmolality and osmolar gap (see p 32; serum levels > 1500 mg/L may increase the osmolar gap by 10 mOsm/L or more), arterial blood gases or oximetry, and ECG monitoring. Valproic acid may cause a false-positive urine ketone determination.

V. Treatment

A. Emergency and supportive measures

1. Maintain an open airway and assist ventilation if needed (see pp 1–7). Administer supplemental oxygen.
2. Treat coma (see p 19), hypotension (p 16), and seizures (p 22) if they occur. Corticosteroids, hyperventilation, barbiturates, and osmotic agents have been used anecdotally to treat cerebral edema.
3. Treat acidosis, hypocalcemia, or hyponatremia if they are severe and symptomatic.
4. Monitor patients for at least 6 hours after ingestion and for up to 12 hours after ingestion of Depakote (divalproex sodium) because of the potential for delayed absorption.

B. Specific drugs and antidotes. There is no specific antidote. Naloxone (see p 469) has been reported to increase arousal, but inconsistently, with greatest success in patients with serum valproic acid levels of 185–190 mg/L. L-Carnitine (p 426) has been used to treat valproic acid–induced hyperammonemia.

C. Decontamination (see p 47)

1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because valproic acid may cause abrupt onset of CNS depression and, in some patients, paradoxical seizures.
2. **Hospital.** Administer activated charcoal. Consider gastric lavage for large ingestions. Moderately large ingestions (eg, > 5–10 g) theoretically require extra doses of activated charcoal to maintain the desired charcoal:drug ratio of 10:1. The charcoal is not given all at once, but in repeated 25- to 50-g quantities over the first 12–24 hours. The addition of **whole-bowel irrigation** (see p 52) may be helpful in large ingestions of sustained-release products such as divalproex (Depakote or Depakote ER).

D. Enhanced elimination (see p 54). Although valproic acid is highly protein bound at therapeutic serum levels, saturation of protein binding in overdose (binding decreases to 35% at 300 mg/L) makes valproic acid favorably disposed to enhanced removal methods.

1. **Hemodialysis and hemoperfusion.** Hemodialysis may result in a four- to tenfold decrease in elimination half-life in overdose patients. Dialysis also corrects metabolic disturbances and removes valproic acid metabolites. Consider dialysis in patients with serum valproic acid levels exceeding 850 mg/L, since these cases are associated with higher morbidity and mortality. Charcoal hemoperfusion (alone and in series with hemodialysis) has also been utilized with clearances similar to those observed with hemodialysis.
2. **Continuous arteriovenous hemofiltration (CAVH)** has also been used but with lower reported clearances.
3. **Repeat-dose activated charcoal.** Theoretically, repeated doses of charcoal may enhance clearance by interruption of enterohepatic recirculation, but no controlled data exist to confirm or quantify this benefit. Another benefit is enhanced gastrointestinal decontamination after large or massive ingestion, since single doses of charcoal are inadequate to adsorb all ingested drug.

Hicks LK, McFarlane PA: Valproic acid overdose and haemodialysis. *Nephrol Dial Transplant* 2001;16(7):1483–1486. [PMID: 11427646] (Case report with peak VPA level 998 mg/L had reduction in half-life from 23.5 h to 2.25 h with hemodialysis. Includes review of the literature.)

Spiller HA et al: Multicenter case series of valproic acid ingestion: serum concentrations and toxicity. *J Toxicol Clin Toxicol* 2000;38(7):755–760. Erratum in: *J Toxicol Clin Toxicol* 2001;39(1):115. [PMID: 11192462] (Peak VPA levels of >450 mg/L were associated with significant clinical effects and >850 mg/L were associated with coma and respiratory depression.)

► VASODILATORS

Shireen Banerji, PharmD

A variety of vasodilators and alpha-receptor blockers are used in clinical medicine. Nonselective alpha-adrenergic blocking agents (eg, phenoxybenzamine, phentolamine, and tolazoline) have been used in clinical practice since the 1940s. The first selective alpha-1 blocker, prazosin, was introduced in the early 1970s; doxazosin, indoramin, terazosin, trimazosin, urapidil, and tamsulosin (approved for benign prostatic hypertrophy) are newer alpha-1-selective agents. Minoxidil, hydralazine, and diazoxide are direct-acting peripheral vasodilators. Fenoldopam, a benzazepine derivative, is the first selective dopamine-1 receptor agonist approved by the FDA for in-hospital, short-term management of severe hypertension, including malignant hypertension. Nitroprusside (see p 281) and nitrates (p 279) are discussed elsewhere.

- I. **Mechanism of toxicity.** All these drugs dilate peripheral arterioles to lower blood pressure. A reflex sympathetic response results in tachycardia and occasionally cardiac arrhythmias. Prazosin and other newer alpha-1-specific agents are associated with little or no reflex tachycardia; however, postural hypotension is common, especially in patients with hypovolemia.
- II. **Toxic dose.** The minimum toxic or lethal doses of these drugs have not been established. No fatalities have been reported except with indoramin overdose and excessive intravenous doses of phentolamine.
 - A. **Indoramin.** A 43-year-old woman died 6 hours after ingesting 2.5 g; central nervous system stimulation and seizures were also reported.
 - B. **Prazosin.** A young man developed priapism 24 hours after an overdose of 150 mg. A 19-year-old man became hypotensive after taking 200 mg and recovered within 36 hours. Two elderly men ingesting 40–120 mg were found comatose with Cheyne-Stokes breathing and recovered after 15–18 hours.
 - C. **Minoxidil.** Two adults developed profound hypotension (with tachycardia) requiring pressor support following 1.3-g and 3-g ingestions from topical minoxidil solutions.
 - D. **Pharmacokinetics.** See Table II–59, p 381.
- III. **Clinical presentation.** Acute overdose may cause headache, nausea, dizziness, weakness, syncope, orthostatic hypotension, warm flushed skin, and palpitations. Lethargy and ataxia may occur in children. Severe hypotension may result in cerebral and myocardial ischemia and acute renal failure. First-time users of alpha-1 blockers may experience syncope after therapeutic dosing.
- IV. **Diagnosis** is based on a history of exposure and the presence of orthostatic hypotension, which may or may not be accompanied by reflex tachycardia.
 - A. **Specific levels.** Blood levels of these drugs are not routinely available or clinically useful.
 - B. **Other useful laboratory studies** include electrolytes, glucose, BUN, creatinine, and ECG and ECG monitoring.
- V. **Treatment**
 - A. **Emergency and supportive measures**
 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7).
 2. Hypotension usually responds to supine positioning and intravenous crystalloid fluids. Occasionally, pressor therapy is needed (p 16).
 - B. **Specific drugs and antidotes.** There is no specific antidote.
 - C. **Decontamination** (see p 47)
 1. **Prehospital.** Administer activated charcoal if available. Do **not** induce vomiting, because of the risk of hypotension and syncope.
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
 - D. **Enhanced elimination.** There is no clinical experience with extracorporeal drug removal for these agents. Terazosin and doxazosin are long-acting and eliminated 60% in feces; thus, repeat-dose activated charcoal may enhance their elimination.

Farrell SE, Epstein SK: Overdose of Rogaine Extra Strength for Men topical minoxidil preparation. *J Toxicol Clin Toxicol* 1999;37(6):781–783. [PMID: 10584592] (Case report of 3-g overdose resulting in profound hypotension, prolonged tachycardia, and fluid overload leading to pleural effusions.)

► VITAMINS

Kent R. Olson, MD

Acute toxicity is unlikely after ingestion of vitamin products that do not contain iron (when iron is present, see p 230). Vitamins A and D may cause toxicity but usually only after chronic use.

I. Mechanism of toxicity

- A. **Vitamin A.** The mechanism by which excessive amounts of vitamin A produce increased intracranial pressure is not known.
- B. **Vitamin C.** Chronic excessive use and large intravenous doses can produce increased levels of the metabolite oxalic acid. Urinary acidification promotes calcium oxalate crystal formation, which can result in nephropathy or acute renal failure.
- C. **Vitamin D.** Chronic ingestion of excessive amounts of vitamin D enhances calcium absorption and produces hypercalcemia.
- D. **Niacin.** Histamine release results in cutaneous flushing and pruritus.
- E. **Pyridoxine.** Chronic overdose may alter neuronal conduction, resulting in paresthesias and muscular incoordination.

II. Toxic dose

- A. **Vitamin A.** Acute ingestion of more than 12,000 IU/kg is considered toxic. Chronic ingestion of more than 25,000 IU/day for 2–3 weeks may produce toxicity.
- B. **Vitamin C.** Acute intravenous doses of more than 1.5 g and chronic ingestion of more than 4 g/day have produced nephropathy.
- C. **Vitamin D.** Acute ingestion is highly unlikely to produce toxicity. Chronic ingestion in children of more than 5000 IU/day for several weeks (adults > 25,000 IU/day) may result in toxicity.
- D. **Niacin.** Acute ingestion of more than 100 mg may cause dermal flushing reaction.
- E. **Pyridoxine.** Chronic ingestion of 2–5 g/day for several months has resulted in neuropathy.

III. Clinical presentation.

Most acute overdoses of multivitamins are associated with nausea, vomiting, and diarrhea.

- A. Chronic **vitamin A** toxicity is characterized by dry, peeling skin and signs of increased intracranial pressure (headache, altered mental status, and blurred vision; pseudotumor cerebri). Bulging fontanelles have been described in infants. Liver injury may cause jaundice and ascites.
- B. **Vitamin C.** Calcium oxalate crystals may cause acute renal failure or chronic nephropathy.
- C. Chronic excessive use of **vitamin D** is associated with hypercalcemia, producing weakness, altered mental status, gastrointestinal upset, renal tubular injury, and occasionally cardiac arrhythmias.
- D. Chronic excessive use of **vitamin E** can cause nausea, headaches, and weakness.
- E. **Vitamin K** can cause hemolysis in newborns (particularly if they are G6PD deficient).
- F. Acute ingestion of **niacin** but not niacinamide (nicotinamide) may produce unpleasant dramatic cutaneous flushing and pruritus, which may last for a few hours. Chronic excessive use (particularly the sustained-release form) has been associated with hepatitis.
- G. Chronic excessive **pyridoxine** use may result in peripheral neuropathy.

- H. Large doses of **B vitamins** may intensify the yellow color of urine, and **riboflavin** may produce yellow perspiration.
- IV. **Diagnosis** of vitamin overdose is usually based on a history of ingestion. Cutaneous flushing and pruritus suggest a niacin reaction but may be caused by other histaminergic agents.
- A. **Specific levels.** Serum vitamin A (retinol) or carotenoid assays may assist in the diagnosis of hypervitaminosis A. Levels of 25-hydroxy vitamin D are useful in assessing excessive intake. Other serum vitamin concentration measurements are not useful.
- B. **Other useful laboratory studies** include CBC, electrolytes, glucose, BUN, calcium, creatinine, liver transaminases, and urinalysis.
- V. **Treatment**
- A. **Emergency and supportive measures**
1. Treat fluid losses caused by gastroenteritis with intravenous crystalloid solutions (see p 16).
 2. Treat vitamin A-induced elevated intracranial pressure and vitamin D-induced hypercalcemia if they occur.
 3. Antihistamines may alleviate niacin-induced histamine release.
- B. **Specific drugs and antidotes.** There is no specific antidote.
- C. **Decontamination** (see p 47). Usually, gut decontamination is unnecessary unless a toxic dose of vitamin A or D has been ingested, or if the product contains a toxic amount of iron.
1. **Prehospital.** Administer activated charcoal if available. If a delay of more than 60 minutes is expected before charcoal can be given, consider using ipecac to induce vomiting, if it can be administered within a few minutes of exposure and there are no contraindications (see p 49).
 2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly.
- D. **Enhanced elimination.** Forced diuresis, dialysis, and hemoperfusion are of no clinical benefit.

Warner JE et al: Vitamin A in the cerebrospinal fluid of patients with and without idiopathic intracranial hypertension. *Ann Neurol* 2002;52(5):647–650. [PMID: 12402264] (CSF vitamin A levels were significantly higher in patients with idiopathic intracranial hypertension.)

► WARFARE AGENTS—BIOLOGICAL

David Tanen, MD

Biological weapons have been used since antiquity, with documented cases dating back to the 6th century BC when the Assyrians poisoned wells with ergots. In the late 1930s and early 1940s, the Japanese army (Unit 731) experimented on prisoners of war in Manchuria with biological agents that are thought to have resulted in at least 10,000 deaths. Although in 1972 over 100 nations signed the Biological Weapons Convention (BWC), both the Soviet Union and Iraq have admitted to the production of biological weapons and many other countries are suspected of continuing their programs. Today, bioweapons are considered the cheapest and easiest weapons of mass destruction to produce. Some agents that are thought likely to be used include: *Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), *Clostridium botulinum* toxin (botulism), *Variola major* (smallpox), and *Francisella tularensis* (tularemia). All of these agents can easily be weaponized for aerial dispersion.

The effect of a biological weapon on a population can be seen in the recent terrorist attack on the east coast of the United States in September 2001. Anthrax spores were delivered through the mail and resulted in 11 cases of inhalational anthrax and 12 cases of the cutaneous form of the disease. Even on this small scale, the effect on the public health system was enormous, and an estimated 32,000 people received prophylactic antibiotic therapy.

I. Mechanism of toxicity

- A. **Anthrax** spores penetrate the body's defenses by inhalation into terminal alveoli, through exposed skin, or by penetration of the GI mucosa. They are then ingested by macrophages and transported to lymph nodes where germination occurs (may take up to 60 days). The bacteria multiply and produce two toxins, known as "lethal factor" and "edema factor." Lethal factor produces local necrosis and toxemia by stimulating the release of tumor necrosis factor and interleukin-1-beta from macrophages.
- B. **Plague** bacteria (*Yersinia pestis*) penetrate the body's defenses either by inhalation into terminal alveoli or by the bite of an infected flea. Dissemination occurs through lymphatics where the bacteria multiply leading to lymph node necrosis. Bacteremia, septicemia, and endotoxemia result in shock, coagulopathy, and coma. Historically, plague is famous as the "Black Death" of the 14th and 15th centuries, which killed 20–30 million people in Europe.
- C. **Botulinum toxins** cannot penetrate intact skin but can be absorbed through wounds or across mucosal surfaces. Once absorbed, the toxins are carried to presynaptic nerve endings at neuromuscular junctions and cholinergic synapses where they bind irreversibly, impairing the release of acetylcholine.
- D. **Smallpox** virus particles reach the lower respiratory tract, cross the mucosa, and travel to lymph nodes where they replicate and cause a viremia leading to further spread and multiplication in the spleen, bone marrow, and lymph nodes. A secondary viremia occurs, and the virus spreads to the dermis and oral mucosa. Death results from the toxemia associated with circulating immune complexes and soluble variola antigens.
- E. **Tularemia.** *Francisella tularensis* bacteria usually cause infection by exposure to bodily fluids of infected animals or from the bites of ticks or mosquitoes. Aerosolized bacteria can also be inhaled. An initial focal, suppurative necrosis is followed by bacterial multiplication within macrophages and dissemination to lymph nodes, lungs, spleen, liver, and kidneys. In the lungs, the lesions progress to pneumonic consolidation and granuloma formation and can result in chronic interstitial fibrosis.

II. **Toxic doses** are variable but generally extremely small. As few as 10–50 *Francisella tularensis* organisms may cause tularemia, and less than 100 mcg of botulinum toxin can result in botulism.

III. Clinical presentation. See Table II–56.

- A. **Anthrax** may present in three different forms: inhalational, cutaneous, and gastrointestinal. Inhalational is extremely rare, and any case should raise the suspicion of a biological attack. Cutaneous typically follows exposure to infected animals and is the most common form, with over 2000 cases reported annually. Gastrointestinal is rare and follows the ingestion of contaminated meat.
- B. **Plague.** Although plague is traditionally spread through infected fleas, biological weapons programs have sought to increase plague's potential by developing techniques to aerosolize it. Depending on the mode of transmission, there are two forms of plague: bubonic and pneumonic. The *bubonic* form would be seen after the dissemination of the bacteria through infected fleas into a population (this was investigated by the Japanese in the 1930s in Manchuria). Following an aerosolized release, the predominant form would be *pneumonic*.
- C. **Botulism** poisoning is described in more detail on page 136. Patients may present with blurred vision, ptosis, difficulty swallowing or speaking, and dry mouth, with progressive muscle weakness leading to flaccid paralysis and respiratory arrest within 24 hours. Since the toxins act irreversibly, recovery may take months.
- D. **Smallpox** infection causes generalized malaise and fever due to viremia, followed by a characteristic diffuse pustular rash with most of the lesions in the same stage of development.
- E. **Tularemia.** After inhalation, victims may develop nonspecific symptoms resembling any respiratory illness, including fever, nonproductive cough,

TABLE II-56. SELECTED BIOLOGICAL WARFARE AGENTS

Agent	Mode of Transmission	Latency Period	Clinical Effects
Anthrax	Spores can be inhaled, ingested, or cross the skin. No person-to-person transmission, so patient isolation not required. Lethal dose estimated 2500–50,000 spores.	Typically 1–7 days but can be as long as 60 days	<i>Inhaled:</i> fever; malaise; dyspnea; nonproductive cough; hemorrhagic mediastinitis; shock. <i>Ingested:</i> nausea, vomiting, abdominal pain, hematemesis or hematochezia; sepsis. <i>Cutaneous:</i> painless red macule or papule enlarges over days into ulcer, leading to eschar; adenopathy; untreated may lead to sepsis. <i>Treatment:</i> ciprofloxacin, other antibiotics (see text); anthrax vaccine.
Plague	Inhalation of aerosolized bacteria, or inoculation via flea bite or wound. <i>Victims are contagious</i> via respiratory droplets. Toxic dose 100–500 organisms.	1–6 days	Following aerosol attack, most victims would develop pulmonary form: malaise, high fever, chills, headache; nausea, vomiting, abdominal pain; dyspnea; pneumonia; respiratory failure; sepsis and multiorgan failure. Black necrotic skin lesions can result from hematogenous spread. Skin buboes otherwise unlikely unless bacteria inoculated through skin (eg, flea bite, wound). <i>Treatment:</i> tetracycline, aminoglycosides, other antibiotics (see text); vaccine not available.
Smallpox	Virus transmitted in clothing, on exposed skin, as aerosol. Victims most contagious from start of exanthem. Toxic dose 100–500 organisms.	7–17 days	Fever, chills, malaise, headache, vomiting, followed 2–3 days later by maculopapular rash starting on the face and oral mucosa and spreading to trunk and legs. Pustular vesicles are usually in the same stage of development (unlike chickenpox). Death in about 30%, from generalized toxemia. <i>Treatment:</i> vaccinia vaccine; immune globulin (see text).
Tularemia	Inhalation of aerosolized bacteria, ingestion, or inoculation via tick or mosquito bite. Skin and clothing contaminated. Person-to-person transmission not reported. Toxic dose 10–50 organisms if inhaled.	3–5 days (range 1–14)	<i>Inhalation:</i> fever, chills, sore throat, fatigue, myalgias, nonproductive cough, hilar lymphadenopathy, pneumonia with hemoptysis and respiratory failure. <i>Skin:</i> ulcer, painful regional adenopathy, fever, chills, headache, malaise. <i>Treatment:</i> doxycycline, aminoglycosides, fluoroquinolones (see text). Investigational vaccine.
Viral hemorrhagic fevers	Variety of routes, including insect or arthropod bites, handling contaminated tissues, or person-to-person transmission.	Variable (up to 2–3 weeks)	These include <i>Ebola</i> , <i>Marburg</i> , <i>Arenaviruses</i> , <i>Hantavirus</i> , several others. Severe multisystem febrile illness with shock, delirium, seizures, and coma, and diffuse bleeding into skin, internal organs, and body orifices. <i>Treatment:</i> none; isolate victims, provide supportive care.
Botulinum toxins	Toxin aerosolized or added to food or water. Exposed to food or water. Exposed surfaces may be contaminated with toxin. Toxic dose 0.01 mcg/kg for inhalation and 70 mcg for ingestion.	Hours to a few days	See p 136. Symmetric, descending flaccid paralysis with initial bulbar palsies (ptosis, diplopia, dysarthria, dysphagia) progressing to diaphragmatic muscle weakness and respiratory arrest. Dry mouth and blurred vision due to toxin blockade of muscarinic receptors. Toxin cannot penetrate intact skin but is absorbed across mucous membranes or wounds. <i>Treatment:</i> botulinum antitoxin (see p 420).

(continued)

TABLE II-56. SELECTED BIOLOGICAL WARFARE AGENTS (CONTINUED)

Agent	Mode of Transmission	Latency Period	Clinical Effects
Ricin	Derived from castor bean (<i>Ricinus communis</i>), may be delivered as a powder or dissolved in water, and may be inhaled, ingested, or injected.	Onset within 4–6 hours; death usually within 3–4 days.	Nausea, vomiting, abdominal pain, diarrhea, often bloody. Not well absorbed orally. Severe toxicity such as cardiovascular collapse, rhabdomyolysis, renal failure, and death more likely after injection. Lethal dose by injection estimated to be 5–20 mcg/kg. Inhalation might cause congestion, wheezing, pneumonitis. <i>Treatment:</i> supportive. Not contagious, no need to isolate victims. Prophylactic immunization with ricin toxoid and passive postexposure treatment with antiricin antibody have been reported in animals.
Staphylococcal enterotoxin B	Enterotoxin produced by <i>Staphylococcus aureus</i> , may be inhaled or ingested.	Onset as early as 3–4 hours, duration 3–4 days.	Fever, chills, myalgia, cough, dyspnea, headache, nausea, vomiting; symptoms usual onset 8–12 hours after exposure. Treatment: supportive. Victims are not contagious, do not need isolation. Vaccine and immunotherapy effective in animals.
T-2 mycotoxin	Yellow sticky liquid aerosol or dust (alleged “Yellow Rain” in 1970s) poorly soluble in water.	Minutes to hours	Highly toxic tricothecene toxin can cause burning skin discomfort; nausea, vomiting, and diarrhea, sometimes bloody; weakness, dizziness, and difficulty walking; chest pain and cough; gingival bleeding and hematemesis; hypotension; skin vesicles and bullae, ecchymosis, and necrosis. Eye exposure causes pain, tearing, redness. Leukopenia, granulocytopenia, and thrombocytopenia reported. Treatment: supportive. Rapid skin decontamination with copious water, soap; consider using military skin decontamination kit.

headache, myalgias, sore throat, fatigue, and weight loss. Skin inoculation causes an ulcer, painful regional lymphadenopathy, fever, chills, headache, and malaise.

IV. Diagnosis. Recognition of a bioweapon attack will most likely be made retrospectively based on epidemiologic investigations. Specific indicators might include patients presenting with exotic or nonendemic infections, clusters of a particular disease, or infected animals in the region where an outbreak is occurring. A historical example was the downwind pattern of disease and proximity of animal deaths that helped prove that the anthrax outbreak in Sverdlovsk (in the former Soviet Union) in 1979 was caused by the release of anthrax spores from a biological weapons plant.

A. Anthrax

1. Obtain a Gram stain and culture of vesicle fluid and blood. Rapid diagnostic tests (ELISA, PCR) are available at national reference labs.
2. Chest x-ray may reveal widened mediastinum and pleural effusions. Chest CT may reveal mediastinal lymphadenopathy.

B. Plague

1. Obtain a Gram stain of blood, CSF, lymph node, or sputum. Other diagnostic tests include direct fluorescent antibody testing and PCR for antigen detection.
2. Chest x-ray may reveal patchy or consolidated bilateral opacities.

C. Botulism (see also p 136)

1. The toxin may be present on nasal mucous membranes and detected by ELISA for 24 hours after inhalation. Refrigerated samples of serum, stool, or gastric aspirate can be sent to the CDC or specialized public health labs that can run a mouse bioassay.
2. Electromyogram (EMG) may reveal normal nerve conduction velocity, normal sensory nerve function, a pattern of brief, small-amplitude motor potentials, and most distinctively, an incremental response to repetitive stimulation often seen only at 50 Hz.

D. Smallpox virus can be isolated from the blood and scabs and can be seen under light microscopy as Guarnieri bodies or by electron microscopy. Cell culture and PCR may also be employed.

E. Tularemia

1. Obtain blood and sputum cultures. *F. tularensis* may be identified by direct examination of secretions, exudates, or biopsy specimens using direct fluorescent antibody or immunohistochemical stains. Serology may retrospectively confirm the diagnosis.
2. Chest x-ray may reveal evidence of opacities with pleural effusions consistent with pneumonia.

V. Treatment. Contact the **Centers for Disease Control (CDC) 24-hour Emergency Response Hotline at (770) 488-7100** for assistance with diagnosis and management.

A. Emergency and supportive measures

1. Provide aggressive supportive care. Treat hypotension (see p 16) with intravenous fluids and vasopressors, and respiratory failure (p 6) with assisted ventilation.
2. **Isolate** patients with suspected plague, smallpox, or viral hemorrhagic fevers, who may be highly contagious. Patient isolation is not needed for suspected anthrax, botulism, or tularemia since person-to-person transmission is not likely. However, health care workers should always use universal precautions.

B. Specific drugs and antidotes

1. **Antibiotics** are indicated for suspected anthrax, plague, or tularemia. All three bacteria are generally susceptible to fluoroquinolones, tetracyclines, and aminoglycosides. The following drugs and doses are often recommended as *initial empiric treatment*, pending results of culture and sensitivity testing (see also *MMWR* 2001 Oct 26;50(42):909–919, which is avail-

able on the Internet at <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5042a1.htm>.

- a. **Ciprofloxacin**, 400 mg IV every 12 h (children: 20–30 mg/kg/day up to 1 g/day).
 - b. **Doxycycline**, 100 mg PO or IV every 12 h (children 45 kg: 2.2 mg/kg).
Note: May discolor teeth in children under 8 years old.
 - c. **Gentamicin**, 5 mg/kg IM or IV once daily, or streptomycin.
 - d. Antibiotics should be continued for 60 days in patients with anthrax infection. **Postexposure antibiotic prophylaxis** is recommended after exposure to anthrax, plague, and tularemia.
 - e. Antibiotics are **not** indicated for ingested or inhaled botulism; aminoglycosides can make muscle weakness worse (see p 136). Treat with **botulinum antitoxin** (p 420).
2. **Vaccines.** Anthrax and smallpox vaccines can be used before exposure and also for postexposure prophylaxis. A pentavalent (ABCDE) botulinum toxoid is currently used for laboratory workers at high risk of exposure. It is **not** effective for postexposure prophylaxis. Vaccines are not currently available for plague, tularemia, or viral hemorrhagic fevers.
- C. **Decontamination.** **Note:** Clothing and skin of exposed individuals may be contaminated with spores, toxin, or bacteria. Rescuers and health care providers should take precautions to avoid secondary contamination.
1. Remove all potentially contaminated clothing, and wash the patient thoroughly with soap and water.
 2. Dilute bleach (0.5%) and ammonia are effective for cleaning surfaces possibly contaminated with viruses and bacteria.
 3. All clothing should be cleaned with hot water and bleach.
- D. **Enhanced elimination.** These procedures are not relevant.

► WARFARE AGENTS—CHEMICAL

Mark Galbo, MS, and Michael A. Miller, MD

Concerns about the possible use of chemical agents in acts of terrorism have increased in the decade since the nerve agent Sarin caused a mass casualty incident in the Tokyo subway system. Chemical warfare poisons include nerve agents, vesicants, cyanides, riot control agents, and pulmonary irritants. Presenting symptoms as well as the clinical circumstances may help identify the agent and lead to effective treatment as well as proper decontamination.

I. Mechanism of toxicity

- A. **Nerve agents** include GA (Tabun), GB (Sarin), GD (Soman), GF, and VX. These potent organophosphorous agents cause inhibition of acetylcholinesterase and subsequent excessive muscarinic and nicotinic stimulation (see p 291).
- B. **Vesicants (blister agents).** Nitrogen and sulfur mustards and Lewisite are cytotoxic alkylating agents; Lewisite combines with thiol moieties in many enzymes and also contains trivalent arsenic.
- C. **Choking or lacrimator agents and riot control agents** are highly irritating gases and liquid mists that react with moist mucous membranes to cause local pain, tearing, cough, and wheezing.

- D. Cyanides** include cyanide, hydrogen cyanide, and cyanogen chloride. These compounds have high affinity for metalloenzymes such as cytochrome aa3, thus derailing cellular respiration and forcing the use of anaerobic metabolism and the development of lactic acidosis.
- E. Incapacitating agents** may be chemical or nonchemical (eg, noise, microwaves, high-intensity light). A variety of agents have been considered, including strong anticholinergic agents such as BZ or scopolamine (see Anticholinergics, p 84); stimulants such as amphetamines, metrazole, or strychnine; hallucinogens such as LSD (p 247); and CNS depressants such as opioids (p 286). A form of fentanyl gas may have been used by Russian authorities in 2002 in an attempt to free hostages from a Moscow theater.
- II. Toxic doses** vary widely and also depend on physical properties of the agents as well as the route and duration of exposure. Apart from the mechanism of toxicity of the chemical weapon itself, the following are important for consideration:
- A. Physical state of the chemical.** Agents delivered as aerosols and in large droplets will generally have more persistence and can accumulate on surfaces. Gases tend to disperse, while vaporized forms of liquids may reliquefy in a cooler environment, leading to potential for delayed dermal exposure. The use of high-molecular-weight thickeners to decrease evaporation of substances has been shown to increase agent persistence.
- B. Volatility.** Highly volatile agents (eg, hydrogen cyanide) vaporize rapidly and can be easily inhaled, while chemicals with low volatility (eg, VX) can remain in the environment for long periods.
- C. Environmental factors.** The presence of wind and rain can reduce the effectiveness of chemical weapon delivery by increasing dispersion and dilutional effects. Cold weather may reduce vapor formation but increase persistence of the liquid form of some agents. Gases and vapors heavier than air may accumulate in low-lying areas.
- D. Agent decomposition** (see also Table II-57). Some warfare agents produce toxic by-products during attempts at decontamination or when exposed to acidic environments. GA may produce hydrogen cyanide and carbon monoxide. GB and GD produce hydrogen fluoride under acidic conditions. Lewisite is corrosive to steel and in nonalkaline conditions may decompose to trisodium arsenate. VX forms the toxic product EA2192 when undergoing alkaline hydrolysis.
- III. Clinical presentation**
- A. Nerve agents** are potent cholinesterase-inhibiting organophosphorus compounds (see also p 291). Symptoms of muscarinic and nicotinic overstimulation include abdominal pain, vomiting, diarrhea, excessive salivation and sweating, bronchospasm, copious pulmonary secretions, muscle fasciculations and weakness, and respiratory arrest. Seizures, bradycardia, or tachycardia may be present. Severe dehydration can result from volume loss due to sweating, vomiting, and diarrhea. Sequelae can include polyneuropathy and neuropsychiatric changes.
- B. Vesicants (blister agents).** The timing of onset of symptoms depends upon the agent, route, and degree of exposure.
1. Skin blistering is the major cause of morbidity and can lead to severe tissue damage.
 2. Ocular exposure causes tearing, itching, and burning, and can lead to severe corneal damage, chronic conjunctivitis, and keratitis.
 3. Pulmonary effects include cough and dyspnea, chemical pneumonia, and chronic bronchitis.
 4. Phosgene oxime (CX) produces urticaria and severe pain.
 5. Mustard exposure may increase the risk of airway cancers.
- C. Choking or lacrimator agents and riot control agents** cause varying degrees of mucous membrane irritation, cough, and wheezing but are generally free of severe or life-threatening effects unless the victim suffers a very large exposure and is unable to escape to fresh air.

TABLE II-57. SELECTED CHEMICAL WARFARE AGENTS

	Appearance	Vapor Pressure and Saturated Air Concentration (at 20–25°C)	Persistence in Soil	Toxic Doses (for 70-kg man)	Comments (see text for additional clinical description)
Nerve agents (cholinesterase inhibitors; see text and p 291)					
Tabun (GA)	Colorless to brown liquid with fairly fruity odor	0.037 mm Hg 610 mg/m ³ Low volatility	1–1.5 days	LC ₅₀ 400 mg-min/m ³ LD ₅₀ skin 1 g	Rapid onset; aging half-time 13–14 hrs
Sarin (GB)	Colorless, odorless liquid	2.1 mm Hg 22,000 mg/m ³ Highly volatile	2–24 hrs	LC ₅₀ 100 mg-min/m ³ LD ₅₀ skin 1.7 g	Rapid onset; aging half-time 3–5 hrs
Soman (GD)	Colorless liquid with fruity or camphor odor	0.4 mm Hg 3,900 mg/m ³ Moderately volatile	Relatively persistent	LC ₅₀ 50 mg-min/m ³ LD ₅₀ skin 350 mg	Rapid onset; aging half-time 2–6 hrs
VX	Colorless to straw-colored odorless liquid	0.0007 mm Hg 10.5 mg/m ³ Very low volatility	2–6 days	LC ₅₀ 10 mg-min/m ³ LD ₅₀ skin 10 mg	Rapid onset; aging half-time 48 hrs
Vesicants					
Sulfur mustard (HD)	Pale yellow to dark brown liquid	0.072 mm Hg 610 mg/m ³ Low volatility	2 weeks–3 years	LC ₅₀ 1500 mg-min/m ³ LD ₅₀ 100 mg/kg	Pain onset hours after exposure; fluid-filled blisters
Phosgene oxime (CX)	Colorless crystalline solid or liquid with intense irritating odor	11.2 mm Hg 1,800 mg/m ³ Moderately volatile	2 hrs	LC ₅₀ 3200 mg-min/m ³ LD ₅₀ unknown	Immediate pain, tissue damage within seconds; solid wheal formation
Lewisite (L)	Colorless to amber or brown oily liquid with geranium odor	0.39 mm Hg 4,480 mg/m ³ Volatile	Days	LC ₅₀ 1200 mg-min/m ³ LD ₅₀ 40–50 mg/kg	Immediate pain, tissue damage in seconds to minutes; fluid-filled blisters

Riot control agents

CS	White crystalline powder with pungent pepper odor	0.00034 mm Hg 0.71 mg/m ³ Very low volatility	Variable	LC ₅₀ 60,000 mg-min/m ³ Incapacitating dose: IC ₅₀ 3–5 mg-min/m ³	Rapid severe eye pain and blepharospasm; skin tingling or burning sensation; duration 30–60 min after leaving exposure
CN (mace)	Solid or powder with fragrant apple-blossom odor	0.0041 mm Hg 34.3 mg/m ³ Low volatility	Short	LC ₅₀ 7–14,000 mg-min/m ³ Incapacitating dose: IC ₅₀ 20–40 mg-min/m ³	
DM (diphenylaminearsine)	Yellow-green odorless crystalline substance	4.5×10^{-11} mm Hg Insignificant Virtually nonvolatile	Persistent	LC ₅₀ 11–35,000 mg-min/m ³ Incapacitating dose: IC ₅₀ 22–150 mg-min/m ³ Nausea & vomiting: 370 mg-min/m ³	Delayed onset (minutes) irritation, uncontrollable coughing and sneezing; vomiting and diarrhea can last hours.

Cyanides (see p 177)

Hydrogen cyanide (AC)	Gas with odor of bitter almonds or peach kernels	740 mm Hg 1,100,000 mg/m ³ Gas lighter than air	Less than 1 hr	LC ₅₀ 2500–5,000 mg-min/m ³ LD ₅₀ skin 100 mg/kg	Rapidly acting gaseous cyanide
Cyanogen chloride (CK)	Colorless gas or liquid	1,000 mm Hg 2,600,000 mg/m ³ Gas density heavier than air	Nonpersistent	LC ₅₀ 11,000 mg-min/m ³	Irritating to eyes and lungs, can cause delayed pulmonary edema

Incapacitating agents (see p 373)

- D. **Cyanides** cause dizziness, dyspnea, confusion, agitation, and weakness, with progressive obtundation and even coma. Seizures and hypotension followed by cardiovascular collapse may occur.
 - E. **Incapacitating agents.** The clinical features depend on the agent (see I. E, above).
 - F. **Anticholinergics.** As little as 1.5 mg of scopolamine can cause delirium, poor coordination, stupor, tachycardia, and blurred vision. BZ (3-quinuclidinyl benzilate, or QNB) is about 3 times more potent than scopolamine. The mouth is usually dry, skin is flushed, and pupils are dilated.
 - G. **LSD** and similar hallucinogens cause dilated pupils, tachycardia, CNS stimulation, and varying degrees of emotional and perceptual distortion.
 - H. **CNS stimulants** can cause acute psychosis, paranoia, tachycardia, sweating, and seizures.
 - I. **CNS depressants** generally cause somnolence and depressed respiratory drive (with apnea a serious risk).
- IV. **Diagnosis** is based mainly upon symptoms as well as the setting in which the exposure occurred.
- A. **Specific levels**
 - 1. **Nerve agents.** Plasma and RBC cholinesterase activity is depressed, but interpretation may be difficult because of the wide interindividual variability and broad normal range (see also p 291).
 - 2. **Pulmonary agents and vesicants.** There are no specific blood or urine levels that will assist in diagnosis or management.
 - 3. **Cyanides.** Cyanide levels will be elevated but rapid testing is not widely available. Suspect cyanide poisoning if the patient has severe metabolic acidosis, especially if mixed venous oxygen saturation is greater than 90%.
 - B. **Other laboratory tests** include CBC, electrolytes, glucose, BUN, creatinine, arterial blood gases, amylase/lipase and liver transaminases, chest x-ray, and ECG monitoring. In addition, obtain serum lactate and mixed venous oxygen saturation if cyanide poisoning is suspected (see p 177).
 - C. **Methods of detection** The military has developed various devices to detect commonly known chemical warfare agents encountered in liquid or vapor forms. These include individual soldier detection systems such as **M8 and M9 paper** (which identifies persistent and nonpersistent nerve or blister agents) and more sophisticated chemical agent detector kits such as the **M256A1 kit**, which can identify a larger number of liquids or vapors. Systems that monitor air concentrations of various agents also have been used, such as the US military's ICAM (chemical agent monitor). Complexity and portability vary widely among detection methods: M9 paper may simply identify that an agent is present, while the Chemical Biological Mass Spectrometer Block II analyzes air samples using a mass spectrometer. Further development of such systems is underway in both the private and governmental/military sectors.
- V. **Treatment.** For expert assistance in management of chemical agent exposures and to access pharmaceutical antidote stockpiles that may be needed, contact your local or state health agency or regional Metropolitan Medical Response System (MMRS). In addition, if an act of terrorism is suspected, contact the Federal Bureau of Investigation (FBI).
- A. **Emergency and supportive measures. *Caution:*** Rescuers and health care providers should take measures to prevent direct contact with the skin or clothing of contaminated victims, because secondary contamination and serious illness may result. (See Section IV, pp 514 and 515).
 - 1. Maintain an open airway and assist ventilation if necessary (see pp 1–7). Administer supplemental oxygen. Monitor patients closely: airway injury may result in abrupt obstruction and asphyxia. Muscle weakness due to nerve agents may cause abrupt respiratory arrest. Delayed pulmonary edema may follow exposure to less soluble gases such as phosgene (p 305).

2. Treat hypotension (see p 16), seizures (p 22), and coma (p 19) if they occur.

B. Specific drugs and antidotes

1. Nerve agents (see also p 291)

- a. **Atropine.** Give 0.5–2 mg IV initially (see p 412), and repeat the dose frequently as needed. Large cumulative doses of atropine (up to 100 mg or more) may occasionally be required in severe cases. The most clinically important indication for continued atropine administration is persistent wheezing or bronchorrhea. **Note:** Atropine will reverse muscarinic but not nicotinic (muscle weakness) effects.
- b. **Pralidoxime** (2-PAM, Protopam; see p 492) is a specific antidote for organophosphorus agents. It should be given immediately to reverse muscular weakness and fasciculations: 1–2 g initial bolus dose (20–40 mg/kg in children) IV over 5–10 minutes, followed by a continuous infusion (p 492). It is most effective if started early, before irreversible phosphorylation of the enzyme, but may still be effective if given later.
- c. The initial doses of atropine and pralidoxime can also be given by the intramuscular route if IV access is not immediately available.
- d. **Alternative oximes.** Oximes such as HI-6 and HI-7 offer promise for better reactivation of cholinesterases in the setting of nerve agent exposure. The availability of these agents in the United States is currently very limited.

2. Vesicants. Treat primarily as a chemical burn (see p 157).

- a. British anti-Lewisite (BAL, see p 413), a chelating agent used in the treatment of arsenic, mercury, and lead poisoning, was originally developed for treatment of Lewisite exposures. It has a number of serious side effects including hypertension and tachycardia. Topical BAL has been recommended for eye and skin exposure to Lewisite; however, preparations for ocular and dermal use are not widely available.
- b. Sulfur donors such as sodium thiosulfate have shown promise in animal models of mustard exposures when given prior to or just after the exposure. The role of this antidote in human exposures is not yet clear.

3. Pulmonary agents and riot control agents. There are no specific antidotes.

4. Cyanides (see p 177). The **cyanide antidote package** (Taylor Pharmaceuticals) consists of amyl and sodium **nitrites** (p 476), which produce cyanide-scavenging methemoglobinemia, and sodium **thiosulfate** (p 505), which accelerates the conversion of cyanide to thiocyanate.

5. Incapacitating agents

- a. Anticholinergic delirium may respond to physostigmine (see p 489).
- b. Stimulant toxicity and bad reactions to hallucinogens may respond to lorazepam, diazepam, or other benzodiazepines (see p 415).
- c. Treat suspected opioid overdose with naloxone (p 469).

C. Decontamination. **Note:** Rescuers should wear appropriate chemical protective clothing, as some agents can penetrate clothing and latex gloves. Butyl chemical protective gloves should be worn, especially in the presence of mustard agents. Preferably, a well-trained hazardous materials team should perform initial decontamination prior to transport to a health care facility (see Section IV, pp 515–516). Decontamination of exposed equipment and materials may also be necessary but can be difficult because agents may persist or even polymerize on surfaces. Currently, the primary methods of decontamination are physical removal and chemical deactivation of the agent. Gases and vapors, in general, do not require any further decontamination other than simple physical removal of the victim from the toxic environment. Off-gassing is unlikely to cause a problem unless the victim was thoroughly soaked with a volatile liquid.

1. **Physical removal** involves removal of clothing, dry removal of gross contamination, and flushing exposed skin and eyes with copious amounts of

water. The **M291 kit** employed by the US military for individual decontamination on the battlefield uses ion-exchange resins and adsorbents to enhance physical removal of chemical agents prior to dilution and chemical deactivation. It consists of a carrying pouch containing six individual pads impregnated with a resin-based powder. The **M258A1 kit** contains two types of packets for removal of liquid chemical agents, one for the G-type nerve agents (Packet 1), and the other for nerve agent VX and liquid mustard (Packet 2).

2. **Chemical deactivation of chemical agents.** Nerve agents typically contain phosphorous groups and are subject to deactivation by hydrolysis, while mustard and VX contain sulfur moieties subject to deactivation via oxidation reactions. Various chemical means of promoting these reactions have been utilized.

- a. **Oxidation.** Dilute sodium or calcium hypochlorite (0.5%) can oxidize susceptible chemicals. This alkaline solution is useful for both organophosphorous compounds and mustard agents. **Caution:** *Dilute hypochlorite solutions should NOT be used for ocular decontamination, nor for irrigation of wounds involving the peritoneal cavity, brain, or spinal cord.* A 5% hypochlorite solution is used for equipment.

- b. **Hydrolysis.** Alkaline hydrolysis of phosphorous-containing nerve agents is an effective means of decontamination of personnel exposed to these agents (VX, Tabun, Sarin, Soman). Dilute hypochlorite is slightly alkaline. The simple use of water with soap to wash an area may also cause slow hydrolysis.

- D. **Enhanced elimination.** There is no role for these procedures in managing illness due to chemical warfare agents.

► WARFARIN AND RELATED RODENTICIDES

Ilene B. Anderson, PharmD

Dicumarol and other natural anticoagulants are found in sweet clover. Coumarin derivatives are used both therapeutically and as rodenticides. Warfarin (Coumadin) is widely used as a therapeutic anticoagulant, but is no longer popular as a rodenticide because rats and mice have become resistant. The most common anticoagulant rodenticides available today contain long-acting “**superwarfarins**” such as brodifacoum, diphacinone, bromadiolone, chlorophacinone, difenacoum, pindone, and valone, which have profound and prolonged anticoagulant effects.

- I. **Mechanism of toxicity.** All these compounds inhibit hepatic synthesis of the vitamin K–dependent coagulation factors II, VII, IX, and X. Only the synthesis of new factors is affected, and the anticoagulant effect is delayed until currently circulating factors have been degraded. Peak effects are usually not observed for 2–3 days because of the long half-lives of factors IX and X (24–60 hours).

- A. The duration of anticoagulant effect after a single dose of **warfarin** is usually 2–7 days. (See also Table II–59, p 381.)

- B. Superwarfarin** products may continue to produce significant anticoagulation for weeks to months after a single ingestion.
- II. Toxic dose.** The toxic dose is highly variable.
- A.** Generally, a single small ingestion of **warfarin** (eg, 10–20 mg) will not cause serious intoxication (most warfarin-based rodenticides contain 0.05% warfarin). In contrast, chronic or repeated ingestion of even small amounts (eg, 2 mg/day) can produce significant anticoagulation. Patients with hepatic dysfunction, malnutrition, or a bleeding diathesis are at greater risk.
- B. Superwarfarins** are extremely potent and can have prolonged effects even after a single small ingestion (ie, as little as 1 mg in an adult). However, in a large study of accidental superwarfarin ingestions in children, no serious cases of anticoagulation occurred.
- C.** Multiple **drug interactions** are known to alter the anticoagulant effect of warfarin (Table II–58).
- III. Clinical presentation.** Excessive anticoagulation may cause ecchymoses, subconjunctival hemorrhage, bleeding gums, or evidence of internal hemorrhage (eg, hematemesis, melena, or hematuria). The most immediately life-threatening complications are massive gastrointestinal bleeding and intracranial hemorrhage.
- A.** Anticoagulant effects may be apparent within 8–12 hours, but with superwarfarins peak effects are commonly delayed for up to 2 days after ingestion.
- B.** Evidence of continuing anticoagulant effects may persist for days, weeks, or even months with superwarfarin products.
- IV. Diagnosis** is based on the history and evidence of anticoagulant effects. It is important to identify the exact product ingested to ascertain whether a superwarfarin is involved.
- A. Specific levels.** **Brodifacoum** levels are available through commercial laboratories, and may be useful in making the diagnosis and determining the endpoint for vitamin K therapy. Levels less than 4–10 ng/mL are not expected to interfere with coagulation.
- 1.** An anticoagulant effect is best quantified by baseline and daily repeated measurement of the **prothrombin time (PT)** and calculation of the **International Normalized Ratio (INR)**, which may not be elevated until 1–2 days after ingestion. A normal PT 48 hours after exposure rules out significant ingestion.
- 2.** Blood levels of clotting factors II, VII, IX, and X will be decreased, but these specific measurements are not usually necessary.

TABLE II–58. EXAMPLES OF POTENTIAL DRUG INTERACTIONS WITH WARFARIN

Increased anticoagulant effect	Decreased anticoagulant effect
Allopurinol	Barbiturates
Amiodarone	Carbamazepine
Anabolic/androgenic steroids	Cholestyramine
Anticoagulant/antiplatelet drugs	Glutethimide
Chloral hydrate	Nafcillin
Cimetidine	Oral contraceptives
Disulfiram	Phenytoin
Ginkgo biloba	Rifampin
Nonsteroidal anti-inflammatory agents	
Quinidine	
Salicylates	
Sulfonamides	

Note: This list represents *only a small sample* of drugs that may interfere with warfarin’s pharmacokinetics and anticoagulant action.

- B. Other useful laboratory studies** include CBC and blood type and cross-match. The partial thromboplastin time (PTT) and platelet count may be useful in ruling out other causes of bleeding.

V. Treatment

- A. Emergency and supportive measures.** If significant bleeding occurs, be prepared to treat shock with transfusions of blood and fresh frozen plasma, and obtain immediate neurosurgical consultation if intracranial bleeding is suspected.

1. Take care not to precipitate hemorrhage in severely anticoagulated patients; prevent falls and other trauma. If possible, avoid use of nasogastric or endotracheal tubes or central intravenous lines.
2. Avoid drugs that may enhance bleeding or decrease metabolism of the anticoagulant (see Table II-58).

- B. Specific drugs and antidotes.** **Vitamin K₁** (phytonadione, see p 508), but **not vitamin K₃** (menadione), effectively restores the production of clotting factors. It should be given if there is evidence of significant anticoagulation. **Note**, however, that if it is given prophylactically after an acute ingestion, the 48-hour prothrombin time cannot be used to determine the severity of the overdose, and it is suggested that the patient be monitored for a minimum of 5 days after the last vitamin K₁ dose.

1. Because vitamin K will not begin to restore clotting factors for 6 or more hours (peak effect 24 hours), patients with active hemorrhage may require **fresh frozen plasma** or **fresh whole blood**.
2. Administer **oral vitamin K₁** every 6 hours (see p 508). Doses of up to 600 mg daily have been required to maintain a satisfactory INR. Vitamin K can also be administered SQ or IV, but these routes are not recommended. **Caution:** Vitamin K-mediated reversal of anticoagulation may be dangerous for patients who require constant anticoagulation (eg, for prosthetic heart valves). Very minute doses should be given if a partial effect is desired.
3. **Prolonged dosing** of vitamin K may be required for several weeks in patients who have ingested a long-acting superwarfarin product.

- C. Decontamination** (see p 47)

1. **Prehospital.** Administer activated charcoal if available.
2. **Hospital.** Administer activated charcoal. Gastric emptying is not necessary if activated charcoal can be given promptly, and should be avoided in the person who is already anticoagulated.

- D. Enhanced elimination.** There is no role for enhanced elimination procedures.

Bruno GR et al: Long-acting anticoagulant overdose: brodifacoum kinetics and optimal vitamin K dosing. *Ann Emerg Med* 2000;36(3):262-267. [PMID: 10969235] (Case report with elevated INR [38.2] and brodifacoum level [179 ng/mL] after intentional ingestion of eight 43-g boxes of rodenticide containing 0.005% brodifacoum [17.2 mg].)

Ingels M et al: A prospective study of acute, unintentional, pediatric superwarfarin ingestions managed without decontamination. *Ann Emerg Med* 2002;40(1):73-78. [PMID: 12085076] (Prospective poison center study of 545 children with unintentional superwarfarin ingestion concludes that gut decontamination and routine measurement of the PT/INR are not necessary.)

TABLE II-59. PHARMACOKINETIC DATA^a

Drug	Onset (hr)	Peak (hr)	Half-Life (hr)	Active Metabolite	Half-Life of Active Metabolite (hr)	Vd (L/kg)	% Protein Binding	Enhanced Elimination	Comments

^aData provided are based on therapeutic dosing, not overdose. In general, after overdose the peak effect is delayed and the half-life and duration of effect are prolonged. Changes may occur in the volume of distribution and the percent protein bound. Kinetics may vary depending on the formulation.

Key to abbreviations: S = sustained-release formulations are available, and may lead to delayed absorption and prolonged effect; HD = hemodialysis; HP = hemoperfusion; PD = peritoneal dialysis; CHP = charcoal hemoperfusion; MDAC = multiple dose activated charcoal; CVVHD = continuous veno venous hemodiafiltration; CAVHD = continuous arteriovenous hemofiltration.

The apparent volume of distribution (Vd) is reported in liters per kilogram (L/kg) unless the field specifically states liters only (L). Table compiled by Ilene B. Anderson, PharmD.

SECTION III. Therapeutic Drugs and Antidotes

Thomas E. Kearney, PharmD

INTRODUCTION

This section provides detailed descriptions of antidotes and other therapeutic agents used in the management of a poisoned patient. For each agent, a summary is provided of its pharmacologic effects, clinical indications, adverse effects and contraindications, usage in pregnancy, dosage, available formulations, and recommended minimum stocking levels for the hospital pharmacy. This section covers agents routinely utilized in the management of poisoning and has been augmented to include antidotal treatment for agents used in chemical and nuclear terrorism and for exotic snake venoms, as well as some antidotes not commercially available in the United States.

I. Use of antidotes in pregnancy. It is always prudent to avoid or minimize drug exposure during pregnancy, and physicians are often reluctant to use an antidote for fear of potential fetal harm. This reluctance, however, must be tempered with a case-by-case risk-benefit analysis of use of the particular therapeutic agent. An acute drug overdose or poisoning in pregnancy may threaten the life of the mother as well as the fetus, and the antidote or therapeutic agent, despite unknown or questionable effects on the fetus, may have lifesaving benefit. The inherent toxicity and large body burden of the drug or toxic chemical involved in the poisoning may far exceed that of the indicated therapeutic agent or antidote.

With most agents discussed in this section, there is little or no information regarding their use in pregnant patients. The **Food and Drug Administration (FDA)** has established five categories of required labeling to indicate the potential for teratogenicity (see Table III-1). The distinction between categories depends mainly on the amount and reliability of animal and human data and the risk-benefit assessment for use of the agent. Note that the categorization may be based on anticipated chronic or repeated use and may not be relevant to a single or brief antidotal treatment.

II. Hospital stocking. The hospital pharmacy should maintain the medical staff-approved stock of antidotes and other emergency drugs. Surveys of hospitals have consistently demonstrated inadequate stocks of antidotes. Many antidotes are used only infrequently, have a short shelf life, or are expensive. There have also been disruptions and delays in the supply of antidotes from manufacturers. Optimal and the most cost-effective case management of poisonings, however, requires having adequate supplies of antidotes readily available. Fortunately, only a minimal acquisition and maintenance cost is required to adequately stock many of these drugs. Other cost reduction strategies may include: employment of an institutional approval and utilization review process (eg, requiring local poison center approval for use of select costly antidotes), seeking arrangements with suppliers to replace expired and unused antidotes (note some manufacturers have such an existing policy), and redistribution of soon-to-expire antidotes.

A. The basis for our **suggested minimum stocking level** is a combination of factors to anticipate the highest total dose of a drug generally given during a 24-hour period as quoted in the literature, the maximum manufacturer's recommended or tolerated daily dose, and estimation of these quantities for a 70-kg adult.

B. Larger quantities of a drug might be needed in unusual situations (eg, chemical terrorism), particularly if multiple patients are treated simultaneously or for extended periods of time. Hospitals in close proximity may wish to explore the practicality of sharing or pooling of stocks, but should carefully consider the logistics of such arrangements (eg, transferring stocks after hours or on weekends). Hospitals should be linked with regional emergency response plans for

TABLE III–1. FDA PREGNANCY CATEGORIES FOR TERATOGENIC EFFECTS

FDA Pregnancy Category	Definition
A	Adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in the first trimester, and there is no evidence of a risk in later pregnancy. The possibility of fetal harm appears remote.
B	Either (1) animal reproduction studies have failed to demonstrate any adverse effect (other than a decrease in fertility), but there are no adequate and well-controlled studies in pregnant women or (2) animal studies have shown an adverse effect that was not confirmed by adequate and well-controlled studies in pregnant women. The possibility of fetal harm is probably remote.
C	Either (1) animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled human studies or (2) there are no animal or human studies. The drug should be given only if the potential benefit outweighs the potential risk to the fetus.
D	There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or human studies, but the potential risks may be acceptable in light of potential benefits (eg, use in a life-threatening situation for which safer drugs are ineffective or unavailable).
X	Studies in animals or humans have demonstrated fetal abnormalities, or there is positive evidence of fetal risk based on human experience, or both, and the risk of using the drug in a pregnant patient outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

► **ACETYL CYSTEINE (N-ACETYL CYSTEINE [NAC])**

Thomas E. Kearney, PharmD

- I. **Pharmacology.** Acetylcysteine (*N*-acetylcysteine [NAC]) is a mucolytic agent that acts as a sulfhydryl group donor, substituting for the liver’s usual sulfhydryl donor, glutathione. It rapidly binds (detoxifies) the highly reactive electrophilic intermediates of metabolism or it may enhance the reduction of the toxic intermediate, NAPQI, to the parent, acetaminophen. It is most effective in preventing acetaminophen-induced liver injury when given early in the course of intoxication (within 8 to 10 hours), but may also be of benefit in reducing the severity of liver injury by several proposed mechanisms (improved blood flow and oxygen delivery, modified cytokine production, free radical or oxygen scavenging) even when given after 24 hours. This proposed role of NAC as a glutathione precursor, direct sulfhydryl binding agent, and antioxidant has also been the basis for its investigational use for poisonings from agents associated with a free radical or oxidative stress mechanism of toxicity or that bind to sulfhydryl groups. It may be used empirically when the severity of ingestion is unknown or serum concentrations of the ingested drug are not immediately available.

II. **Indications**

- A. Acetaminophen overdose.

- B. Case reports of or investigational use in carbon tetrachloride, chloroform, acrylonitrile, doxorubicin, arsenic, gold, amanitin mushroom, carbon monoxide, chromium, cyanide, paraquat, and methyl mercury poisoning.
- C. Pennyroyal oil poisoning (case reports). The mechanism of hepatic injury by pennyroyal oil is similar to that of acetaminophen, and empiric use of NAC seems justified for any significant pennyroyal oil ingestion.
- D. Cisplatin nephrotoxicity and prevention of radiocontrast-induced nephropathy.

III. Contraindications. Known hypersensitivity (rare).

IV. Adverse effects

- A. Acetylcysteine typically causes nausea and vomiting when given **orally**. If the dose is vomited, it should be repeated. The dose calculation and proper dilution (to 5%) should be verified (this effect may be dose and concentration dependent). Use of a gastric tube, slower rate of administration, and a strong antiemetic agent (eg, metoclopramide, p 467; ondansetron, p 481) may be necessary.
- B. Rapid **intravenous** administration can cause flushing, rash, angioedema, hypotension, and bronchospasm (anaphylactoid reaction). One death was reported in a small child rapidly receiving a large dose intravenously, as well as another in an adult with severe asthma. Reactions can be minimized by giving each dose slowly over 60 minutes in a dilute (3–4%) solution (this effect is dose and concentration dependent) and exercising extreme caution in asthmatics (avoid IV use or carefully titrate with more dilute solutions and slower infusion rates).
- C. **Use in pregnancy.** FDA category B. There is no evidence for teratogenicity. Use of this drug to treat acetaminophen overdose is considered beneficial to both mother and developing fetus.

V. Drug or laboratory interactions

- A. Activated charcoal adsorbs acetylcysteine and may interfere with its systemic absorption. When both are given orally together, data suggest that peak acetylcysteine levels are decreased by about 30% and that the time to reach peak level may be delayed. However, these effects are not considered clinically important.
- B. NAC can produce a false-positive test for ketones in the urine.

VI. Dosage and method of administration

- A. **Oral loading dose.** Give 140 mg/kg of the 10% or 20% solution diluted to 5% in juice or soda to enhance palatability.
- B. **Maintenance oral dose.** Give 70 mg/kg every 4 hours. The commonly accepted protocol for treatment of acetaminophen poisoning in the United States calls for 17 doses of oral NAC given over approximately 72 hours. However, successful protocols in Canada, the United Kingdom, and Europe utilize intravenous NAC for only 20 hours. We initially give NAC orally until 36 hours have passed since the time of ingestion (of acetaminophen). Then, if the serum acetaminophen level is below the limits of detection and liver transaminase levels are normal, NAC can be stopped. If there is evidence of hepatic toxicity, NAC should be continued until resolution of toxic effects (ie, liver function tests are clearly improving).
- C. Although **intravenous administration** is not FDA approved in the United States, it can be used when recurrent vomiting prevents oral administration despite generous doses of antiemetics. One or two doses of IV NAC are usually required, and then the oral regimen can be resumed. Contact a medical toxicologist or regional poison center ([800] 222-1222) for advice and see the formulations section below for preparation and administration. A 48-hour investigational protocol showed safety and efficacy with the same doses and intervals as for oral administration. In the United Kingdom, the dosing regimen is 150 mg/kg in 200 mL of 5% dextrose in water (D5W) over 15 minutes (death in an obese asthma patient occurred with this regimen, and the dose

was based on total body weight), followed by 50 mg/kg in 500 mL of D5W over 4 hours and then 100 mg/kg in 1000 mL of D5W over 16 hours.

- D. Dosage during dialysis.** Although acetylcysteine is removed during dialysis, no change in dosage is necessary.
- E. Dosage for prevention of radiocontrast-induced nephropathy.** Give 600 mg of PO NAC twice on the day before and the day of the procedure (4 doses total). This is coupled with IV hydration using 1/2 NS at 1 mL/kg/h for 12 hours before and after the administration of the contrast agent.

VII. Formulations

- A.** The usual formulation is as a 10% (100-mg/mL) or 20% (200-mg/mL) solution, supplied as an inhaled mucolytic agent (Mucomyst, Mucosil, or generic). This form is available through most hospital pharmacies or respiratory therapy departments. This preparation is **not** FDA approved for parenteral use. In rare circumstances when intravenous administration of this preparation is required, dilute the dose to a 3–4% solution (In D5W), use a micropore (0.22-micron) filter, and give the dose over 45–60 minutes.
- B.** In the United States, an investigational intravenous formulation may be available at medical centers participating in an approved study.
- C. Suggested minimum stocking level** for treatment of a 70-kg adult for the first 24 hours: 20% solution, 7 vials (30 mL each).

► ANTIVENOM, CROTALINAE (RATTLESNAKE)

Richard F. Clark, MD

- I. Pharmacology.** Two antivenoms are now available for the treatment of crotaline envenomation in the United States. The older product is Crotalinae polyvalent antivenom (equine) (Antivenom Crotalinae Polyvalent, Wyeth-Ayerst), while the newer product is Crotalinae polyvalent immune Fab (ovine) (CroFab, Protherics). To produce these antivenoms for rattlesnake venom, horses or sheep are hyperimmunized with pooled venom of various snakes (*Crotalus adamanteus*, *C atrox*, *C durissus terrificus*, and *B atrox* for the Wyeth product, while *C scutulatus* and *A piscivorus* are substituted for the latter two in the Protherics product). The lyophilized protein product from these pooled animal sera is a combination of several antibodies against venom constituents and often contains residual serum components. CroFab™ is composed of Fab fragments of the original antibodies, derived by adding papain to the pooled, affinity-purified serum product. After administration, the antivenom is distributed widely throughout the body, where it binds to venom.
- II. Indications.** Antivenom is used for treatment of significant envenomation by Crotalinae species (see Section II, p 343).
- III. Contraindications.** Known hypersensitivity to the antivenom or to horse serum is a relative contraindication for the Wyeth product; antivenom may still be indicated for severe envenomation despite a patient history of allergic reaction. Known hypersensitivity to sheep or sheep serum, or to papain or papayas, are contraindications for the Protherics product (CroFab).
- IV. Adverse effects**
 - A.** Immediate hypersensitivity reactions (including life-threatening anaphylaxis) may occur from both products, even in patients with no history of horse serum sensitivity and negative skin test results. Skin testing is not indicated with CroFab, and immediate hypersensitivity reactions appear to be less common.
 - B.** Mild flushing and wheezing often occur within the first 30 minutes of intravenous administration and often improve after slowing the rate of infusion.
 - C.** Delayed hypersensitivity (serum sickness) occurs in over 75% of patients receiving more than four vials of Wyeth antivenom and in virtually all patients

who receive more than 12 vials. Onset occurs in 5–14 days. CroFab™ administration can also lead to delayed hypersensitivity reactions, but may be less common than with the Wyeth product.

- D. Use in pregnancy.** FDA category C (indeterminate). There are no data on teratogenicity. Anaphylactic reaction resulting in shock or hypoxemia in the mother could conceivably adversely affect the fetus.

V. Drug or laboratory interactions. There are no known interactions.

VI. Dosage and method of administration. The initial dose is based on severity of symptoms, not on body weight (Table III–2). Children may require doses as large as or larger than those for adults. The endpoint of antivenom therapy is the reversal of systemic manifestations (eg, shock, coagulopathy, and paresthesias) and the halting of progressive edema and pain. Antivenom may be effective up to 3 days or more after envenomation. If you suspect envenomation by the Mojave rattlesnake (*Crotalus scutulatus*) and symptoms are present, especially an increased serum creatine phosphokinase (CPK) level, administer 10 vials of Wyeth antivenom or 4 vials of CroFab even when there is minimal swelling or local pain.

- A.** Treat all patients in an intensive care or monitored setting.

- B.** Before skin tests or antivenom administration, insert at least one and preferably two secure intravenous lines.

- C.** Perform the skin test for horse serum sensitivity for the Wyeth product, using a 1:10 dilution of antivenom (some experts prefer this method) or the sample of horse serum provided in the antivenom kit (follow package instructions). Do **not** perform the skin test unless signs of envenomation are present and imminent antivenom therapy is anticipated. If the skin test is positive, reconsider the need for antivenom as opposed to supportive care, but do not abandon antivenom therapy if it is needed. Even if the skin test is negative, anaphylaxis may still occur unpredictably.

- D.** If antivenom is used in a patient with a positive skin test, pretreat with intravenous diphenhydramine (see p 436) and cimetidine (or another H₂ blocker; see p 428), and have ready at the bedside a preloaded syringe containing epinephrine (1:10,000 for intravenous use) in case of anaphylaxis. Dilute the antivenom 1:10 to 1:1000 before administration, and give each vial very slowly at first (ie, over 30–45 minutes), increasing the rate of infusion as tolerated.

- E.** Reconstitute the lyophilized vial of either product with the 10 mL of diluent provided or sterile saline and gently swirl for 10–30 minutes to solubilize the material. Avoid shaking, which may destroy the immunoglobulins (indicated by foam formation). Further dilution with 50–200 mL of saline may facilitate solubilization.

- F.** Administer antivenom by the intravenous route only. Start slowly, increasing the rate as tolerated. In nonallergic individuals, 5–10 vials of Wyeth antivenom or 4–6 vials of CroFab can be diluted in 250–500 mL saline and given over 60–90 minutes.

TABLE III–2. INITIAL DOSE OF CROTALINAE ANTIVENOM

Severity of Envenomation	Initial Dose (vials)	
	Antivenom Crotalinae Polyvalent (Wyeth)	CroFab (Protherics)
None or minimal	None	None
Mild (local pain and swelling)	5	4
Moderate (proximal progression of swelling, ecchymosis, mild systemic symptoms)	10	4–6
Severe (hypotension, rapidly progressive swelling and ecchymosis, coagulopathy)	15	8

- G. If inadequate response to initial dose, give an additional 4 vials of CroFab (5–10 vials of Wyeth) over 60 minutes, or give an additional 6 vials of CroFab if signs of severe envenomation are still present. Repeat in 4- to 6-vial increments (5–10 vials of Wyeth) per hour until progression of symptoms is halted.
- H. Recurrence of symptoms of envenomation may occur with use of either antivenom, but may be more common with CroFab due to shorter half-life of the Fab molecule. Recurrence following CroFab is usually manifested 12–24 hours after stabilization is achieved with the initial dosing of CroFab. Repeating laboratory tests and observing for progression of swelling is therefore recommended for 24 hours or more when CroFab antivenom is used. The repeat administration of CroFab in 2-vial (or more if needed) increments is recommended if recurrence occurs. As an alternative, the package insert suggests consideration of repeat 2-vial dosing every 6 hours for 3 additional doses in severe envenomations.

VII. Formulations

- A. **Antivenom Crotalinae (formerly Crotalidae) polyvalent or Crotalinae polyvalent immune Fab.** Supplies can be located by a regional poison center ([800] 222-1222).
- B. The **suggested minimum stocking level** to treat a 70-kg adult for the first 24 hours is 20 vials of Wyeth antivenom or 12 vials of CroFab.

► ANTIVENOM, *LATRODECTUS MACTANS* (BLACK WIDOW SPIDER)

Richard F. Clark, MD

- I. **Pharmacology.** To produce the antivenom, horses are hyperimmunized with *Latrodectus mactans* (black widow spider) venom. The lyophilized protein product from pooled equine sera contains antibodies specific to certain venom fractions, as well as residual serum proteins such as albumin and globulins. After intravenous administration, the antivenom distributes widely throughout the body, where it binds to venom.
- II. **Indications**
 - A. Black widow envenomation–induced severe hypertension or muscle cramping not alleviated by muscle relaxants, analgesics, or sedation; consider particularly in patients at the extremes of age (ie, younger than 1 year or older than 65 years).
 - B. Black widow envenomation in **pregnancy** may cause abdominal muscle spasms severe enough to threaten spontaneous abortion or early onset of labor.
- III. **Contraindications.** Known hypersensitivity to horse serum.
- IV. **Adverse effects**
 - A. Immediate hypersensitivity may occur rarely, including life-threatening anaphylaxis.
 - B. Delayed-onset serum sickness may occur after 10–14 days, but is rare owing to the small volume of antivenom used in most cases.
 - C. **Use in pregnancy.** FDA category C (indeterminate). There are no data on teratogenicity. An anaphylactic reaction resulting in shock or hypoxemia in the mother could conceivably adversely affect the fetus.
- V. **Drug or laboratory interactions.** No known interactions.
- VI. **Dosage and method of administration.** Generally, one vial of antivenom is sufficient to treat black widow envenomation in adults or children.
 - A. Treat all patients in an emergency department or intensive care setting.
 - B. Before a skin test or antivenom administration, insert at least one and preferably two secure intravenous lines.

- C. Perform a skin test for horse serum sensitivity, by using a 1:10 dilution of antivenom (some experts prefer this method) or the sample of horse serum provided in the antivenom kit (according to package instructions). Do **not** perform the skin test unless signs of envenomation are present and imminent antivenom therapy is anticipated. If the skin test is positive, reconsider the need for antivenom as opposed to supportive care, but do not abandon antivenom therapy if it is needed. Even if the skin test is negative, anaphylaxis may still occur unpredictably.
- D. If antivenom is used in a patient with horse serum sensitivity, pretreat with intravenous diphenhydramine (see p 436) and cimetidine (or another H₂ blocker; see p 428), and have ready at the bedside a preloaded syringe containing epinephrine (1:10,000 for intravenous use) in case of anaphylaxis. Dilute the antivenom (1:10 to 1:1000) and administer it very slowly in these cases.
- E. Reconstitute the lyophilized product to 2.5 mL with the supplied diluent, using gentle swirling for 15–30 minutes to avoid shaking and destroying the immunoglobulins (indicated by the formation of foam).
- F. Dilute this solution to a total volume of 10–50 mL with normal saline.
- G. Administer the diluted antivenom slowly over 15–30 minutes. One or two vials are sufficient in most cases.

VII. Formulations

- A. Lyophilized antivenom (*L. mactans*), 6000 units, contains 1:10,000 thimerosal as a preservative.
- B. The **suggested minimum stocking level** to treat a 70-kg adult for the first 24 hours is one vial.

► ANTIVENOM, *MICRURUS FULVIUS* (CORAL SNAKE), AND EXOTIC ANTIVENOMS

Richard F. Clark, MD

- I. **Pharmacology.** To produce the antivenom, horses are hyperimmunized with venom from *Micrurus fulvius*, the eastern coral snake. The lyophilized protein preparation from pooled equine sera contains antibodies to venom fractions as well as residual serum proteins. Administered intravenously, the antibodies distribute widely throughout the body where they bind the target venom.
- II. **Indications**
 - A. Envenomation by the eastern coral snake (*M. fulvius*) or the Texas coral snake (*M. fulvius tener*).
 - B. **May not be effective** for envenomation by the western, Arizona, or Sonora coral snake (*M. euryxanthus*).
- III. **Contraindications.** Known hypersensitivity to the antivenom or to horse serum is a relative contraindication; if a patient with significant envenomation needs the antivenom, it should be given with caution.
- IV. **Adverse effects**
 - A. Immediate hypersensitivity, including life-threatening anaphylaxis, may occur even after a negative skin test for horse serum sensitivity.
 - B. Delayed hypersensitivity (serum sickness) may occur 1–3 weeks after antivenom administration, the severity depending on the total quantity of antivenom administered.
 - C. **Use in pregnancy.** FDA category C (indeterminate). There are no data on teratogenicity. Anaphylactic reactions resulting in shock or hypoxemia in expectant mothers could conceivably adversely affect the fetus.
- V. **Drug or laboratory interactions.** There are no known interactions.
- VI. **Dosage and method of administration.** Generally, the recommended initial dose is three to five vials. The drug is most effective if given before the onset of signs or symptoms of envenomation. An additional three to five vials may be

given, depending on the severity of neurological manifestations but not on body weight (children may require doses as large as or even larger than those for adults).

A. Treat all patients in an intensive care unit setting.

B. Before a skin test or antivenom administration, insert at least one and preferably two secure intravenous lines.

C. Perform a skin test for horse serum sensitivity, using a 1:10 dilution of antivenom (some experts prefer this method) or the sample of horse serum provided in the antivenom kit (according to package instructions). If the skin test is positive, reconsider the need for antivenom as opposed to supportive care, but do not abandon antivenom therapy if it is needed. Even if the skin test is negative, anaphylaxis may still occur unpredictably.

D. If antivenom is used in a patient with a positive skin test, pretreat with intravenous diphenhydramine (see p 436) and cimetidine (or another H₂ blocker; p 428) and have ready at the bedside a preloaded syringe containing epinephrine (1:10,000 for intravenous use) in case of anaphylaxis. Dilute the antivenom (1:10 to 1:1000) and administer very slowly in these cases.

E. Reconstitute the lyophilized material with 10 mL of the diluent supplied, gently swirling for 10–30 minutes. Avoid shaking the preparation because this may destroy the immunoglobulins (indicated by the formation of foam). Dilution with 50–200 mL of saline may aid solubilization.

F. Administer the antivenom intravenously over 15–30 minutes per vial.

VII. Exotic antivenoms. Companies outside of the United States produce a variety of antivenoms for exotic snakebites. Most of these treat snakebites by elapids, since this family of snakes causes the most severe envenomations worldwide. The vast majority are still whole-antibody products derived from horses. A few are produced as Fab fragments, or the slightly larger Fab₂ molecule (cleaved with pepsin instead of papain). All of the whole-antibody preparations carry the same risk of immediate and delayed allergy as US-produced whole-IgG antivenoms. Envenomation by exotic elapids, such as cobras, mambas, and all the poisonous snakes of Australia, would be expected to produce the same or worse degree of neurotoxicity as seen in coral snakes from this country, and require antivenom administration as soon as possible. It is likely that many snakebites from snakes within the same family would respond to antivenom made from venom of another snake in that family. Therefore, if type-specific antivenom is not available for a severe snakebite, same-family antivenom may be substituted with some possible efficacy. Regional poison centers ([800] 222-1222) may be able to assist in obtaining exotic antivenoms from collectors or zoos.

VIII. Formulations

A. Antivenom (*M fulvius*) vial of lyophilized powder with 0.25% phenol and 0.005% thimerosal as preservatives.

B. Suggested minimum stocking level to treat a 70-kg adult for the first 24 hours is 5–10 vials.

► APOMORPHINE

Thomas E. Kearney, PharmD

I. Pharmacology. Apomorphine is an alkaloid salt derived from morphine that has minimal analgesic properties but marked emetic efficacy. Vomiting is produced by direct stimulation of the medullary chemoreceptor trigger zone. After subcutaneous administration, emesis occurs within an average of 5 minutes; oral administration is **not** recommended because of erratic absorption.

II. Indications. Apomorphine was previously used for induction of emesis in the acute management of oral poisoning, but it has been abandoned because of its potential for respiratory depression and its inconvenient formulation (soluble

tablets for parenteral injection). The drug is not discussed further in this book, but it remains popular in veterinary practice.

► ATROPINE AND GLYCOPYRROLATE

Richard J. Geller, MD, MPH

- I. Pharmacology.** Atropine and glycopyrrolate are parasympatholytic agents that competitively block the action of acetylcholine at muscarinic receptors. Important differences between the drugs include the fact that atropine crosses the blood-brain barrier, while glycopyrrolate does not, a structural difference which makes an allergic reaction to one drug unlikely to occur in the other (a lack of cross-sensitivity), and a relative lack of tachycardia caused by glycopyrrolate. Desired therapeutic effects for treating poisoning include decreased secretions from salivary and other glands, decreased bronchorrhea and wheezing, decreased intestinal secretion and peristalsis, increased heart rate, and enhanced atrioventricular conduction. The elimination half-life of atropine is 2–4 hours (longer in children) with approximately 50% excreted unchanged in urine. Glycopyrrolate is primarily excreted unchanged in the bile and urine.

II. Indications

- A. Correction of bronchorrhea and excessive oral and GI tract secretions associated with organophosphate and carbamate insecticide intoxication. Glycopyrrolate may be especially useful to manage peripheral cholinergic symptoms in cholinesterase inhibitor poisoning, as it will not cause the CNS side effects seen with large doses of atropine (although it will not reverse CNS toxicity associated with cholinesterase inhibitor poisoning).
- B. Acceleration of the rate of sinus node firing and atrioventricular nodal conduction velocity in the presence of drug-induced atrioventricular conduction impairment (eg, caused by digitalis, beta blockers, calcium antagonists, organophosphorus or carbamate insecticides, or physostigmine).
- C. Reversal of central (by atropine) and peripheral (by atropine and glycopyrrolate) muscarinic symptoms in patients with intoxication by *Clitocybe* or *Inocybe* mushroom species.
- D. When neostigmine or pyridostigmine is used to reverse nondepolarizing neuromuscular blockade, glycopyrrolate is the preferred agent to block unwanted muscarinic effects (neuromuscular blockers, see p 472).

III. Contraindications

- A. Patients with hypertension, tachyarrhythmias, thyrotoxicosis, congestive heart failure, coronary artery disease, and other illnesses, who might not tolerate a rapid heart rate. Patients with severe cholinesterase inhibitor poisoning are often tachycardic. Atropine should not be withheld and may lower heart rate (by improving oxygenation). Glycopyrrolate may also be helpful (due to its lessened propensity to cause a tachycardia).
- B. Angle-closure glaucoma in which papillary dilation may increase intraocular pressure. (May be used safely if the patient is being treated with a miotic.)
- C. Partial or complete obstructive uropathy.
- D. Myasthenia gravis.
- E. Obstructive diseases of the GI tract, severe ulcerative colitis, bacterial infections of the GI tract.

IV. Adverse effects

- A. Some adverse effects include dry mouth, blurred vision, cycloplegia, mydriasis, palpitations, tachycardia, aggravation of angina, and constipation. Urinary retention is common, and a Foley catheter may be needed. Duration of effects may be prolonged (several hours). Additionally, CNS anticholinergic toxicity (delirium) may occur with large doses of atropine needed to treat cholinesterase inhibitor poisoning.

- B. Atropine doses of less than 0.5 mg (in adults) and those administered by very slow intravenous push may result in paradoxical slowing of heart rate.
- C. **Use in pregnancy.** Atropine is FDA category C (indeterminate). It readily crosses the placenta. However, this does not preclude its acute, short-term use for a seriously symptomatic patient (see p 405). Glycopyrrolate is FDA category B, and crosses the placenta poorly.

V. Drug or laboratory interactions

- A. Atropinization may occur more rapidly if atropine and pralidoxime are given concurrently to patients with organophosphate or carbamate insecticide poisoning.
- B. Atropine and glycopyrrolate have an additive effect with other antimuscarinic and antihistaminic compounds.
- C. Slowing of gastrointestinal motility may delay absorption of orally ingested materials.

VI. Dosage and method of administration

A. Organophosphate or carbamate insecticide poisoning

1. **Atropine.** For adults, begin with 1–5 mg IV; for children, give 0.02 mg/kg IV. (The drug may also be given via the intratracheal route: dilute the dose in normal saline to a total volume of 1–2 mL.) Repeat this dose every 5–10 minutes until satisfactory atropinization is achieved. Note that severely poisoned patients may require exceedingly higher doses (eg, up to 100 mg over a few hours) of atropine determined by clinical titration and control of muscarinic symptoms.
2. **Glycopyrrolate.** Initial IV dose for adults is 1–2 mg (children: 0.025 mg/kg).
3. **Therapeutic endpoints.** The goal of therapy is drying of bronchial secretions (this endpoint may be reached prematurely if the patient is dehydrated) and reversal of wheezing and significant bradycardia. Recrudescence of symptoms may occur, and in severe poisonings several grams of atropine may be required and may be administered by constant intravenous infusion or with larger bolus doses and/or more frequent intervals (eg, 3–5 minutes).

- B. **Drug-induced bradycardia.** Atropine is usually the drug of choice in this circumstance. For adults, give 0.5–1 mg IV; for children, give 0.02 mg/kg IV up to a maximum of 0.5 mg and 1 mg in adolescents. Repeat as needed. Note that 3 mg is a fully vagolytic dose in adults. If response is not achieved by 3 mg, the patient is unlikely to benefit from further treatment unless bradycardia is caused by excessive cholinergic effects (eg, carbamate or organophosphate overdose).

VII. Formulations

- A. **Parenteral.** Atropine sulfate injection, 0.05-, 0.1-, 0.3-, 0.4-, 0.5-, 0.6-, 0.8-, 1-, and 1.2-mg/mL solutions. Use preservative-free formulations when massive doses are required. Glycopyrrolate injection (Robinul, others), 0.2 mg/mL in 1-, 2-, 5-, and 20-mL vials (some with 0.9% benzyl alcohol).
- B. The **suggested minimum stocking level** to treat a 70-kg adult for the first 24 hours is 1 g atropine and 20 mg glycopyrrolate (higher amounts may be needed if sole antimuscarinic agent).

► BAL (DIMERCAPROL)

Michael J Kosnett, MD, MPH

- I. **Pharmacology.** BAL (British anti-Lewisite, dimercaprol, 2,3-dimercaptopropanol) is a dithiol chelating agent used in the treatment of poisoning by the heavy metals arsenic, mercury, lead, and gold. Because the vicinal thiol groups are unstable in aqueous solution, the drug is supplied as a 10% solution (100

mg/mL) in peanut oil that also contains 20% (200 mg/mL) benzyl benzoate. It is administered by deep intramuscular injection. Most of the drug is absorbed within 1 hour, and undergoes widespread distribution to most tissues. BAL, or its in vivo biotransformation product(s), is believed to form complexes with selected toxic metals, thereby minimizing the metal's reaction with endogenous ligands, and increasing its excretion in the urine. In a study of humans treated with BAL after exposure to arsenicals, peak urinary arsenic excretion occurred in 2–4 hours, and then rapidly declined.

II. Indications

- A. Acute inorganic **arsenic** poisoning. Limited data suggest it may also be useful in the early stages of arsine poisoning (ie, during the first 24 hours).
- B. **Mercury** poisoning (except monoalkyl mercury). BAL is most effective in preventing renal damage if administered within 4 hours after acute ingestion of inorganic mercury salts; its value in averting or treating the acute or chronic neurological effects of elemental mercury vapor is unknown.
- C. **Lead** poisoning (except alkyl lead compounds). BAL has been used concomitantly with calcium EDTA (p 440) in the treatment of pediatric lead encephalopathy, where the joint regimen has been associated with accelerated decline in blood lead levels and increased urinary lead excretion. **Note:** BAL is not for use as a single drug regimen in lead poisoning.
- D. **Gold.** BAL has been associated with an increase in urinary gold excretion and clinical improvement in patients treated for adverse dermatologic, hematologic, or neurological complications of pharmaceutical gold preparations.

III. Contraindications

- A. Because BAL is dispensed in peanut oil, avoid use in patients with peanut allergy.
- B. Use with caution in patients with hepatic and renal impairment. A few reports suggest that dimercaprol or its metabolites are dialyzable, and that BAL increases the dialysis clearance of mercury in patients with renal failure.
- C. BAL has caused hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency.
- D. Because it is given by intramuscular injection, use with caution in patients with thrombocytopenia or coagulopathies.

IV. Adverse effects

- A. Local pain at injection site; sterile or pyogenic abscess formation.
- B. Dose-related hypertension, with or without tachycardia. Onset, 15–30 minutes; duration, 2 hours. Use with caution in hypertensive patients.
- C. **Other adverse symptoms.** Nausea and vomiting, headache; burning sensations in the eyes, lips, mouth, and throat sometimes accompanied by lacrimation, rhinorrhea, or salivation; myalgias; paresthesias; fever (particularly in children); a sensation of constriction in the chest; and generalized anxiety. Central nervous system depression and seizures have occurred in overdose.
- D. **Use in pregnancy.** FDA category C (indeterminate) (see p 405). High doses of BAL are teratogenic and embryotoxic in mice. The safety of BAL in human pregnancy is not established, although it has been used in a pregnant patient with Wilson's disease without apparent harm. It should be used in pregnancy only for life-threatening acute intoxication.
- E. **Redistribution of metals to the brain.** Despite its capacity to increase survival in acutely poisoned animals, BAL has been associated with redistribution of mercury and arsenic into the brain. Avoid use in chronic elemental mercury poisoning or alkyl (eg, methyl) mercury poisoning, where the brain is a key target organ.

V. Drug or laboratory interactions

- A. Because a toxic complex with iron may be formed, avoid concurrent iron replacement therapy.
- B. BAL may abruptly terminate gold therapy–induced remission of rheumatoid arthritis.

VI. Dosage and method of administration (adults and children)

- A. Arsenic, mercury, and gold poisoning.** Give BAL, 3 mg/kg deep intramuscular injection (IM) every 4–6 hours for 2 days, then every 12 hours for up to 7–10 days if patient remains symptomatic and/or metal levels remain highly elevated. In patients with severe arsenic or mercury poisoning, an initial dose of up to 5 mg/kg may be used. Consider changing to oral succimer (p 501) or oral unithiol (p 506) once patient is stable and able to absorb an oral formulation. **Note:** Intravenous unithiol (see p 506) has a more favorable therapeutic index than BAL, and may be a preferable alternative in the treatment of acute arsenic or mercury intoxication.
- B. Lead encephalopathy** (only in conjunction with calcium EDTA therapy [see p 440]). For acute pediatric lead encephalopathy, some clinicians initiate treatment with BAL, 3–4 mg/kg IM (75 mg/m^2), followed in 4 hours by concomitant use of calcium EDTA and BAL, 3–4 mg/kg (75 mg/m^2) every 4–6 hours for up to 3 days.
- C. Arsine poisoning** (see p 119). Consider the use of BAL, 3 mg/kg IM every 4–6 hours for 1 day, if it can be begun within 24 hours of the onset of arsine poisoning.
- D. Lewisite burns to the eye.** Create a 5% solution of BAL by diluting the 10% ampule 1:1 in vegetable oil, and *immediately* apply to the surface of the eye and conjunctivae. Parenteral treatment may also be necessary to treat systemic effects (see p 372).

VII. Formulations

- A. Parenteral** (for deep IM injection only; must **not** be given as IV). BAL in oil, 100 mg/mL, 3-mL ampules.
- B.** The **suggested minimum stocking level** to treat a 70-kg adult for the first 24 hours is 1800 mg (six ampules).

► BENZODIAZEPINES (DIAZEPAM, LORAZEPAM, AND MIDAZOLAM)

Thomas E. Kearney, PharmD

I. Pharmacology

- A.** Benzodiazepines potentiate inhibitory gamma-aminobutyric acid (GABA) neuronal activity in the central nervous system. Pharmacologic effects include reduction of anxiety, suppression of seizure activity, central nervous system depression (possible respiratory arrest when given rapidly intravenously), and inhibition of spinal afferent pathways to produce skeletal muscle relaxation.
- B.** In addition, diazepam has been reported to antagonize the cardiotoxic effect of chloroquine (the mechanism is unknown, but diazepam may compete with chloroquine for fixation sites on cardiac cells).
- C.** Benzodiazepines generally have little effect on the autonomic nervous system or cardiovascular system.
- D. Pharmacokinetics.** All agents are well absorbed orally, but diazepam is not well absorbed intramuscularly. The drugs are eliminated by hepatic metabolism, with serum elimination half-lives of 1–50 hours. The duration of central nervous system effects is determined by the rate of drug redistribution from the brain to peripheral tissues. Active metabolites further extend the duration of effect of diazepam.
